To Lindy Lou: my partner, my friend, my strength

—LRK

I would very much like to dedicate this volume to my partners and our staff at The University of Virginia. Without their help and support, all the amazing things we are able to do for our patients would not occur. I would also like to very much thank the residents that I have had the honor of teaching over these years. Their dedication to the care of our patients makes my job the best in the world.

—ILK

To Diane.

Much has changed in the field of cardiothoracic surgery since the appearance of the second edition of Mastery of Cardiothoracic Surgery. Our field has become further fragmented (not necessarily a bad thing, by the way) with the creation of certification in congenital heart surgery following a period of additional training in a certified center. There no longer is a single textbook that covers the entire field, but we now have texts covering adult cardiac, general thoracic, and congenital cardiac. Aortic surgery has emerged as a specialty unto itself within cardiothoracic surgery and cardiac surgical education now is expected to incorporate endovascular training specifically related to the thoracic aorta, though the field of vascular surgery clearly overlaps in this area. There is now a primary certificate in vascular surgery offered in select centers, and completion of this program qualifies one to apply for entry into a residency in cardiothoracic surgery. Needless to say, those who come to cardiothoracic surgery by way of primary training in vascular surgery certainly bring a different perspective, though it remains too early to determine how these individuals will influence the specialty.

Despite the fragmentation with many programs having separate general thoracic and cardiac tracks, the specialty remains as one from the perspective of the American Board of Thoracic Surgery. The qualifying examination and the certifying examination as well as the examination given for maintenance of certification all include material from each of the specialty areas, a requirement that has engendered some controversy especially as it relates to Maintenance of Certification. It seems counterintuitive to expect a significant knowledge base relating to congenital heart surgery from a diplomat who has practiced, for example, general thoracic surgery for 10 years or more.

Bucking the trend, we have continued to include aspects of the entire specialty in Mastery of Cardiothoracic Surgery, with the assumption that the book will be used by trainees and practicing surgeons alike whether to review the aspects of a case prior to doing their first or as a refresher for a case that has not been done for a while. The editors have not wavered from their initial vision, and the vision of the originators of the Mastery series: that of having acknowledged masters of a given technique or procedure tell how they do it sharing their “tricks” and the subtleties learned from experience over the years.

The book is richly illustrated to show in detail how a procedure should be done. We have not set out to add another textbook to the canon; we have attempted to produce a volume that is complementary to the standard texts as well as to the literature. With full-text journal articles including those not yet published in hard copy just as close as the nearest computer, one has to question the relevance of a standard textbook. Yet this book provides what much of the literature does not, the “how to do it” piece. We are extremely proud of this edition as we have added a number of new authors as well as chapters, and have included several more recent procedures, including transcatheter aortic valve replacement. The editors are confident that users of this book will find each chapter of value either prior to doing a procedure or while reviewing the material prior to either the qualifying or Maintenance of Certification examinations.

Larry R. Kaiser, MD
Irving L. Kron, MD
Thomas L. Spray, MD
This book truly has been a labor of love because each of us has plenty to do in our day jobs. The task has not been easy but it is safe to say it would have been impossible without the incredible knowledge, diligence, and patience as well as support from Brendan Huffman who has been with us from the beginning of this edition. We also acknowledge the support and patience of his colleagues at Lippincott Williams & Wilkins and specifically Brian Brown who had the confidence in our abilities to see this through. It has been a pleasure working with them. We also acknowledge the outstanding quality of the work from the authors who contributed to this edition.
I. GENERAL THORACIC SURGERY  1

Chapter 1: Endoscopy: Bronchoscopy and Esophagoscopy  2
Abbas E. Abbas

Chapter 2: Mediastinoscopy and Other Thoracic Staging Procedures  14
Michael Lanuti

Chapter 3: Thoracic Approaches  28
M. Blair Marshall

Chapter 4: Right-Sided Pulmonary Resections  40

Endoscopy: Bronchoscopy and Esophagoscopy
Abbas E. Abbas

INTRODUCTION

Traditional endoscopy allows the evaluation of the endoluminal aspect of the tracheobronchial tree and the foregut. Newer advances such as endosonography and electromagnetic navigation have broadened the scope to include information outside the immediate lumen. The indications have evolved from a simple diagnostic procedure to one that may also be therapeutic or for staging of thoracic malignancies. The impressive technological advances in the field of fiberoptic endoscopy over the last decade now allow us to have access! to areas previously considered “blind” by traditional endoscopy. For example, electromagnetic navigation can help to accurately navigate the bronchoscope to a peripheral lung nodule. Endoscopic ultrasound (EUS) allows us to visually assess a mediastinal lymph node in real time while simultaneously performing a transbronchial fine needle aspiration. Rigid endoscopy, whether esophageal or bronchial, remains as important for the thoracic surgeon to master today as it always has been. Although flexible endoscopy has taken away some of the indications for the rigid procedures, such as dilation and stenting, rigid endoscopy still plays a vital role for the thoracic surgeon and at times may be life-saving. The main advantage of rigid endoscopy is the ability to use larger instruments. This allows better biopsy specimens, debride- ment of tissues, and suctioning of fluids and debris. Rigid endoscopy is also necessary for certain stent placements in the airway. Although it is possible to perform all endoscopic procedures, including even rigid endoscopy, under local anesthesia or with simple sedation, advanced endoscopies are sometimes quite lengthy and safer to perform under general anesthesia. The choice of analgesia and anesthesia should be determined on an individual basis and according to pathology or operator preference.

ANATOMY

It is important for the endoscopist to have a clear understanding of both the endoluminal and the external relationship to overlying mediastinal structures. This is especially important for EUS and this is also where surgeons have a distinct advantage.

Pharynx and Larynx

Aerodigestive anatomy begins with the entry of air into the body via the nasopharynx and the oropharynx. Entry may be gained to the upper aerodigestive system through either the nose or the mouth. At the nares, there is a 3- to 4-mm opening below the lower turbinate, with direct access to the posterior pharynx. This entry is just medial to the pharyngeal tonsil and passes posterior to the soft palate. Entry through the mouth reaches the posterior portion of the tongue is passed, one reaches the vallecula. At this level, the epiglottis can be seen anterior to the aerodigestive tract. Immediately posterior to this structure, the vocal cords can be seen easily. They are attached anteriorly and move apart posteriorly. The vocal cords are bounded by the aryepiglottic fold and posteriorly by the corniculate tubercles. Just posterior to the tubercles is the entrance to the esophagus. Laterally, on both sides of the esophagus, are the pyriform recesses, which are often mistaken for the true esophagus but are false passages with a depth of 2 to 3 cm.

Bronchoscopic Anatomy

A complete bronchoscopic examination will inspect the divisions of the tracheobronchial tree to the level of the segmental and subsegmental orifices.

Trachea

The trachea begins inferior to the glottis, at the level of the sixth cervical vertebra. Distally, it divides into the left and right mainstem bronchi at the carina. The location of the carina is usually at the level of the fifth thoracic vertebra, which is in line with the angle of Louis. This may ascend or descend up to two vertebrae with breathing. The internal diameter is about 16 mm while the length of the trachea varies according to the height of the individual and is about 12 cm. Surgically, the trachea is divided into two parts; the cervical trachea from the glottis to the manubrium and the thoracic trachea from the manubrium to the carina (Fig. 1.1).

The wall of the trachea is formed of fibromuscular tissue which is reinforced anteriorly by 16 to 20 incomplete cartilaginous rings. These rings form the anterior two-thirds of the tracheal circumference. The posterior wall is a flat fibromuscular membrane, which is immediately anterior to the esophagus.

The thoracic trachea is crossed anteriorly by the left innominate vein. Immediately inferior to the vein, it lies behind and to the right of the arch of the aorta and is straddled by the innominate artery on the right and the left common carotid artery on the left. Laterally on the right, the superior vena cava runs longitudinally adjacent to the trachea. Paratracheal and subcarinal lymph nodes lie in direct relationship to the trachea.

Mainstem Bronchi

The right mainstem bronchus (RMSB) arises from the carina at an angle of 30 degrees while the left mainstem bronchus (LMSB) has a sharper turn closer to 45 degrees. The diameter of the RMSB is also larger than the LMSB (16 vs. 13 mm). These are the reasons for the difficulty in intubating the left bronchus compared with the right, and for why inhaled foreign bodies are found more often on the right side.

The RMSB is usually about 1- to 2.5-cm long and ends after giving off the right upper lobe (RUL) branch. Its continuation then becomes the bronchus intermedius.
Bronchoscopic view of the trachea and carina. (BI), which is also about 2-cm long. The RUL bronchus (Fig. 1.2) comes off perpendicularly to the RMSB and gives off three segmental branches. Its location can vary in different individuals and may even arise as a direct branch of the trachea. It is saddled by the azygos vein laterally and lies superior then posterior to the right pulmonary artery. The BI then terminates as a bifurcation to the middle and lower lobe bronchi (Fig. 1.3). The right middle lobe (RML) bronchus usually arises directly opposite to the superior segmental branch of the right lower lobe (RLL), but may be just higher or lower, a relationship that is important to determine when performing lobectomy.

The LMSB (Fig. 1.4) is longer than the right and averages 5 cm. It passes underneath the aortic arch and crosses anterior to the esophagus, the thoracic duct, and the descending aorta. It lies posterior and then inferior to the left pulmonary artery. The bifurcation of the LMSB into the left upper lobe and the left lower lobe bronchi is often called the secondary carina.

Bronchopulmonary Segmentation

Primary branches of the lobar bronchi are called segmental bronchi and each leads to a structurally separate unit called the bronchopulmonary segment (Table 1.1 and Fig. 1.5). These number 10 in the right lung and 8 in the left. The RUL bronchus divides into three segmental bronchi, namely, the apical, posterior, and anterior segments. The RML bronchus divides into the medial and lateral segments. The RLL bronchus divides into the superior segment and four basal segments, including the anterior, medial, lateral, and posterior basal segments. The left upper lobe bronchus divides into an upper division and a lower division. The upper division, or upper lobe proper, gives rise to the apicoposterior and anterior segments. The lower division, or lingual, gives rise to the superior and inferior segmental bronchi. As on the right side, the first segmental branch of the LLL bronchus is a large superior segmental bronchus. This is followed by the basal segments, which number only 3 on the left side; anterior basal segment, the lateral basal segment, and the posterior basal segment.

The Esophagus

The esophagus, or gullet, is a long muscular tube that connects the pharynx to the stomach. The length of the esophagus in adults is about 25 cm and, like the trachea, varies with the length of the individual. It extends from the cricopharyngeus muscle at the level of the cricoid cartilage and the sixth cervical vertebra to the cardiac orifice of the stomach at the level of the 11th thoracic vertebra.

Along its course, the esophagus is in the midline, anterior to the spine except for two leftward curves. At its origin, the esophagus curves gently to the left down to the level of fifth thoracic vertebra where it returns to the midline. The second is a sharper curve to the left and is formed as the esophagus traverses the diaphragm at the hiatus where it turns to cross the descending thoracic aorta and enter into the stomach.
Section I: General Thoracic Surgery

Imbition

Segmental Airway Anatomy

Right

Upper lobe: apical (RB1), posterior (RB2), and anterior (RB3)
Middle lobe: lateral (RB4) and medial (RB5)
Lower lobe: superior segment (RB6), medial basal (RB7), anterior basal (RB8), lateral basal (RB9), and posterior basal (RB10)

Left

Upper lobe

The upper lobe proper bronchus: apicoposterior (LB1 + 2) and the anterior (LB3)
The lingular bronchus: superior (LB4) and inferior (LB5)
Lower lobe: superior segment (LB6), anterior basal (LB8), lateral basal (LB9), and posterior basal (LB10)

There is no medial basal segment (LB7) in the left lung.

The esophagus also follows the convex and then concave curvatures of the cervical and thoracic spine.

In endoscopy, the parts of the esophagus are described according to the distance from the upper incisor teeth. The upper esophageal sphincter (UES), or cricopharyngeus, is at 15 cm whereas the lower esophageal sphincter (LES) is at 40 cm. It is important to remember that these levels can vary depending on the height of the patient and also on the timing when measurements were taken. Measurements made while advancing the endoscope tend to be longer than those made during retraction, a phenomenon commonly seen with a sliding hiatal hernia.

It is also usually divided into cervical, thoracic, and abdominal portions. The cervical portion extends from the cricopharyngeus to the suprasternal notch. The thoracic portion extends from the suprasternal notch to the diaphragm. The abdominal portion extends from the diaphragm to the cardiac portion of the stomach.

The esophagus has three natural constrictions along its course. It is important for the endoscopist to be aware of these locations, especially when searching for impacted foreign bodies or when deciding on the amount of safe dilation for pathologic strictures at those sites. The first constriction is at 15 cm from the incisors, right at the UES and is the narrowest portion of the esophagus. The second is at 23 cm, where the esophagus lies behind the aortic arch and LMSB. The third constriction is at 40 cm, where it traverses the diaphragm at the LES.

Endoscopic Relationships of the Esophagus

It is important to understand the relationships of the esophagus especially when performing EUS or before contemplating certain maneuvers such as dilation and stenting. The cervical esophagus lies posterior to the membranous trachea. It overlies the bodies of sixth, seventh, and eighth cervical vertebra. The bilateral carotid sheath and lateral lobes of thyroid gland are immediately lateral to the cervical esophagus.

The thoracic esophagus lies in the superior mediastinum between the trachea and vertebral column. It then enters the posterior mediastinum by passing behind the aortic arch. Laterally, it is related to the aorta and left subclavian artery on the left while on the right side, it is related to the azygos vein. Anteriorly, the esophagus is related to the trachea, right pulmonary artery, left bronchus, pericardium with left atrium, and diaphragm. Posteriorly, the esophagus is related to the vertebral column, descending aorta, and diaphragm.

The abdominal esophagus passes through the right crus of the diaphragm to lie posterior to the left lobe of the liver.

EQUIPMENT

A modern fiberoptic endoscope (Fig. 1.6) basically consists of a handle and a fiberoptic bundle that connects to a light source. There are also one or more working channels for suctioning and for the passage of instruments or injection of liquids. The handle contains one or more knobs to control the position of the tip of the endoscope. Most current bronchoscopes also have a camera adaptor allowing connection to a high-definition monitor (Fig. 1.7).

Bronchoscopy

In addition to performing the visual inspection, there are various options for obtaining material from a bronchoscopy. Brushes can be used to obtain cytology material. The brush is retracted into a sheath after
Fig. 1.6. Flexible bronchoscope with standard accessories. The endotracheal tube ventilating adaptor, the biopsy forceps, and a disposable brush are shown.

Fig. 1.7. Flexible fiberoptic bronchoscope showing camera adapter, suction port, and biopsy or irrigation port.

brushing to protect the specimen. A biopsy forceps is used to obtain material either under direct visualization from the proximal airway or from the peripheral lung parenchyma under fluoroscopic guidance. A transbronchial needle may be used to obtain extrabronchial samples with or without ultrasound guidance. A triple lumen catheter with a double-sheathed telescoping brush enables sampling of lower respiratory tract secretions for microbiologic examination without contamination from the inner channel of the bronchoscope. This is especially useful in the setting of the possibility of lobar pneumonia. When performing lavage for either cytology or microbiology, irrigation is administered through the working channel and a trap is connected to the suction port.

The endoscope diameter ranges from 3 to 6 mm, with a working channel ranging from 1.2 to 3 mm. For routine diagnostic purposes, a standard 3.5-mm endoscope is usually sufficient. If one plans more extensive procedures, a larger endoscope may be necessary. It is advisable to have a range of sizes to accommodate the planned procedure. Most bronchoscopic procedures require an endotracheal tube of at least 8 mm. A bronchoscopy adapter for the endotracheal tube allows simultaneous ventilation during the procedure.

Rigid Bronchoscopy

Except for minor modifications, today's rigid bronchoscope (Fig. 1.8) is similar to that developed by Chevalier Jackson, the father of American bronchoesosophagology. It is a stainless steel straight and hollow tube that is available in a range of sizes. Rigid bronchoscope external diameters can range up to 14 mm, and the length varies according to the age and size of the patient and have a beveled tip used to elevate the epiglottis and thus expose the vocal cords to facilitate passage. The proximal end of the bronchoscope consists of a central opening, which has a removable eyepiece that can also allow placement of a 4- or 5-mm telescope. This telescope usually has a 0-degree viewing angle to enable wide end-on visualization, while a 90-degree viewing angle may be useful to visualize the right upper lobe bronchus or the superior segmental orifices of the lower lobe.

Slit-like openings in the distal end allow ventilation to the contralateral lung.

Most rigid bronchoscopes also contain a light source at the distal end. The side ports may be used for flexible suction and laser fiber or flexible biopsy forceps.

Esophagoscopy

Rigid esophagoscopy has been an integral part of the practice of thoracic surgery since it was first described in 1868 by Kussmaul. Not long after, Jackson developed the ability to end-illuminate the rigid esophagoscope and since then the instrument has undergone very few modifications and has been used extensively for both diagnostic and therapeutic purposes. The rigid esophagoscope (Figs. 1.9 and 1.10) looks much like a rigid bronchoscope but is flatter and has a more bulbous tip. It is also available in adult and pediatric sizes and can vary in length from 20 to 50 cm. The advantages of rigid esophagoscopy include excellent visualization of the upper esophageal and
Section I: General Thoracic Surgery

Fig. 1.8. Rigid bronchoscope set in two different sizes (with permission from Karlstorz, Inc.). There are two side ports, one for ventilation and a second port for placement of flexible tools. The light source is placed within the wall of the scope. The adapter shown at the bottom can be adjusted to provide a seal around different sized inserts. At the top are shown three optical forceps that incorporate the telescope and allow direct visualization while they are being used.

Fig. 1.9. Standard Jackson esophagoscopes. Each varies slightly in the shape at the end, but in general they are flattened and shaped like the esophagus. Suctions have either an end hole or two side holes.

Fig. 1.10. Dilating esophagoscope. This esophagoscope is round and will accept up to a 36F dilator. Several varieties of Jackson rigid dilators are shown coming out of the end of the scope.

DILATORS AND STENTS

Simple repeated esophageal dilation is the oldest technique for palliation of dysphagia but is rarely associated with long-term relief. Usually, dysphagia recurs after only a few days or weeks. Dilation may be accomplished by using weighted rubber Maloney bougies, wire-guided polyvinyl Savary dilators, or hydrostatic dilating balloons. Maloney dilators (Fig. 1.11) are passed blindly into the esophagus and are quite effective in experienced hands. Savary dilators (Fig. 1.11) are passed over a stiff guide wire, which is inserted under direct vision through the stricture. Successive dilators are passed up to the desired level. Both types of dilators come in diameters ranging from 2 to 20 mm (6F to 60F) and both mm and French size are usually clearly marked on the instrument. They are also marked in centimeters to determine the depth of insertion. These measurements are shown both from the tip (American) and from the widest part (European) of the dilator. Finally, hydrostatic balloon dilators (Fig. 1.12) have been developed that can be passed through the working channel of the endoscope and deployed under vision. They have the same range of diameters available as the rigid dilators. Theoretically, the radial force of a dilating balloon is thought to be safer than the longitudinal force of bougies.

The risk of perforation is higher in very tight lesions and in patients who have had previous radiation therapy. The procedure usually needs to be repeated every few days and is seldom sufficient in producing long-term relief.
Fig. 1.11. Flexible dilators. The Savary dilator (top) is a wire-guided dilator. The Maloney dilators are marked in centimeters to gauge the depth of insertion in both American and European systems (see text).

Fig. 1.12. Controlled radial expansion-fixed wire balloon dilator and inflation device. (b) Inflation device. (Copyright © 2006 Boston Scientific Corporation or its affiliates. All Rights Reserved.)

We prefer using either wire-guided Savary bougies under fluoroscopic guidance or the hydrostatic balloons under direct endoscopic visualization. However, with the availability of self-expanding metal and plastic stents, dilation is rarely used as the sole treatment for dysphagia.

Prior to the advent of self-expanding metal stents (SEMS), the main methods for maintaining the lumen of the esophagus open was in the form of fixed-diameter plastic prostheses, for example, the Celestin or Wilson-Cook stents. These were inserted either using rigid esophagoscopy (push technique) or by pulling through a gastrotomy (pull technique). These have largely been abandoned in favor of the easier to place self-expandable stents.

**Self-Expandable Metal Stents**

SEMS were introduced in 1990 and have now replaced the conventional fixed-diameter plastic prostheses. Numerous studies have shown them to be associated with fewer complications and better efficacy (85% to 100%) than the fixed-diameter plastic stents. In addition, they are much easier to insert, and usually do not require a predilation unless the diameter of the lumen is narrower than that of the delivery system (6 to 11 mm). SEMS (Figs. 1.13A and 1.14A) have a thin wall and a large endoluminal diameter (16 to 23 mm), which ensures effective relief of dysphagia. These stents become embedded into the mucosa and are difficult to remove after several weeks. A silicone or polyurethane coating (Fig. 1.13B) allows stents to resist tumor ingrowth but makes them more prone to migration. They all come preloaded on a small-diameter delivery system (Fig. 1.14B), and when deployed, they exert outward radial force to expand to their full diameter. The radial force of the stent maintains lumen patency, and tumor compression holds the stent in place (Fig. 1.13C). They are all placed in a similar manner, usually over a wire with endoscopic and/or fluoroscopic guidance. They are then deployed by a self-expanding mechanism. They may be placed under either general anesthesia or moderate sedation.

Early complications occur in approximately 10% of patients and include perforation, bleeding, pain, stent migration, and airway obstruction. Perforation is related to the use of excessive force during dilation or passage of the delivery system. Airway obstruction may occur especially in the presence of large cervical or mediastinal adenopathy, which may cause external compression of the trachea after expansion of the stent. This may require emergent stent removal or even placement of a second airway stent.

Late complications include recurrence of dysphagia that may occur due to tumor overgrowth or ingrowth (10% to 15%), granulation tissue hyperplasia or, stent migration (1% to 15%). Food impaction, troublesome gastroesophageal reflux, esophagorespiratory fistula, and bleeding have also been reported with the use of these stents. Tracheoesophageal fistula can result from stent erosion through the esophagus and into the respiratory tree. Massive bleeding may result from a similar process into the aorta.

When tumor ingrowth or overgrowth does occur, it can be managed with several techniques including placement of a second stent within the old one or using a variety of ablation methods including laser, argon plasma coagulation, endoscopic debridement, and photodynamic therapy.

**PROCEDURE**

**Anesthesia**

As mentioned above, the choice of whether to use general anesthesia or sedation with local anesthesia depends on the predicted complexity and duration of the procedure. It is safer to perform a lengthy and complex endoscopic procedure under general anesthesia with the control of the airway and the ability to use muscle relaxants.
Patients undergoing conscious sedation are usually given a combination of a sedative such as midazolam and an analgesic such as meperidine. These agents are given in increments while monitoring the patient carefully. Monitoring includes an electrocardiogram tracing, blood pressure, heart rate, and a pulse oximeter. Supplemental oxygen before, during, and after the procedure is administered.

The local anesthetic administered depends on the procedure. For esophagoscopy, viscous lidocaine gargle or tetracaine spray may be used. For bronchoscopy, lidocaine is sprayed to the pharynx, the vocal cords, the trachea, and throughout the airway, at the orifice of each bronchus. One must be careful not to exceed the maximum dose of the local anesthetic.

For general anesthesia, it is best to use short-acting agents such as propofol and inhalational agents. Muscular relaxants such as succinylcholine may be used when necessary, such as for rigid bronchoscopy.

**BRONCHOSCOPY**

**Flexible Bronchoscopy**

The fiberoptic flexible bronchoscope can be introduced into the airway through different routes. There are distinct advantages and disadvantages to each of these options, and it is important to be both aware and familiar with each. Flexible bronchoscopy may be performed under conscious sedation using either the transnasal or transoral route. If a patient has a tracheostomy stoma, this can also provide a route for bronchoscopy. When general anesthesia is employed, it is possible to perform the procedure through an endotracheal tube, but this allows examination only of the airway distal to the tube, usually just above the carina. An excellent alternative is to perform the procedure through a laryngeal mask airway (LMA), thus allowing full exposure of the glottis and entire airway distally.

When performed under conscious sedation, the operator usually stands behind the patient or on the patient’s right side. For the transoral approach, a bite block is placed around the bronchoscope which is then placed between the incisors after the scope is advanced into the trachea. The transnasal approach is a more direct approach to the larynx while the oral route requires navigating the scope around the tongue and the epiglottis to identify the glottis. Both approaches allow complete visualization of the airway.
After instilling 1 to 2 cm³ of local anesthetic into the larynx, the scope is passed through the vocal cords. Local anesthetic is sprayed at every lobar bronchial orifice before traversing it.

**Procedure**

Careful inspection of the airway is performed on the first pass before any possible distortion by endoscopic scope trauma. The examination should be done on the contralateral side of the suspected pathology to ensure that every part of the airway was examined in a comprehensive and sequential manner. After the initial inspection, any abnormalities that are noted should be addressed in a manner that will confirm their nature. Secretions should be collected in a trap, taking care to prevent contamination by the oropharynx by only attaching the trap once the bronchoscope is in the airway. The choice of the procedure depends upon the circumstances involved. For an endobronchial lesion, both brushing and biopsy should be performed. For a peripheral lung lesion and for interstitial lung disease, a transbronchial lung biopsy is performed. Fluoroscopy is used to advance the biopsy forceps toward the abnormality and to minimize the risk of pneumothorax. The forceps is introduced into the segment to about 3 cm from the ribs. The forceps is opened and advanced while patient is inhaling until it wedges. The forceps is closed and pulled back at the end of expiration. If the patient develops pleuritic pain during the procedure, the forceps is withdrawn slightly until there is no pain. About six biopsy specimens should be obtained to ensure an adequate sample, which should include respiratory epithelium and alveolar wall. The specimens should be sent for routine histology, microbiology, and immunofluorescent staining. The Wang needle is used for transbronchial biopsy (Fig. 1.15). This is usually done at the carina to evaluate the subcarinal lymph nodes. The needle is contained within a sheath that is passed through the working channel of the bronchoscope. It is advanced out of the sheath and through the wall of the airway into the desired extramural mass or lymph node. After several passes, the material obtained is placed on slides for direct cytologic interpretation and into cell fixative for cell block. Some of the materials may also be sent for culture. Bronchoalveolar lavage is done for diffuse lung disease. Washings or lavage is best performed after brushing. The scope is wedged into a segmental or subsegmental bronchus, and about 100 ml of saline is instilled in 20 ml aliquots. At least 50% must be retrieved in a trap for a successful BAL. The fluid is sent for both cytology and microbiology. After completion of the procedure, the entire airway is reinspected for bleeding, which can be easily controlled by instillation of cold saline or small amounts of a 1:10,000 solution of epinephrine. Blood pressure and pulse should be carefully monitored during this procedure because drugs are rapidly absorbed from the respiratory epithelium. When a transbronchial biopsy is performed, a chest radiograph must be obtained following the procedure to rule out a pneumothorax.

**Rigid Bronchoscopy**

**Anesthesia and Ventilation**

General anesthesia is preferred for both comfort and safety. Because the anesthesiologist gives up control of the airway to the surgeon, it is essential to have clear communication between the two throughout the entire procedure. Induction of anesthesia can be done with inhalational agents but once induced, it is preferable to continue to maintain the depth of anesthesia with a total intravenous technique. A muscle relaxant is usually used for the initial intubation with the rigid bronchoscope. Ventilation during the procedure can be through the side port, using breaths delivered by a combination of spontaneous breathing, hand-assistance, and ventilator delivery. It is important to ensure a good seal at the mouth as evidenced by rise of the chest with breaths and end-tidal carbon dioxide monitoring. Jet ventilation is another option in which oxygen and air mixture is delivered through a small side port using a handheld injector. The advantage of jet ventilation is the ability to provide adequate oxygenation with minimal pressure.

**Position**

Positioning the patient correctly is critical for successful rigid bronchoscopy. The patient is placed supine with extension of the neck using a rolled sheet or air bag (Fig. 1.16). This allows the trachea to be as anterior as possible and to also be in direct alignment with the larynx (Fig. 1.16). A guard should be placed over the maxillary front teeth. The videoscope is advanced into the bronchoscope and the bronchoscopist looks either directly down the bronchoscope or at the monitor while the bronchoscope is advanced. The beveled edge should be facing anteriorly toward the tongue. While advancing the scope, the left hand should be used to stabilize it and also to protect the teeth, which should never be used as a fulcrum for the scope. Another technique for insertion is by using a laryngoscope to elevate the tongue.

Once the uvula is in view, the beveled tip is used to lift the epiglottis, thus exposing the vocal cords. The bronchoscope is then rotated 90 degrees to allow its narrowest edge, the bevel, to advance in between the cords. Once in the trachea, it is rotated back so that the beveled tip is once more anterior. Advancing the scope through the trachea should be done with a gentle cork-screw motion of the right hand, while the left hand is used as a fulcrum to stabilize the scope and protect the teeth.

Another method to insert the rigid bronchoscope is by using a Miller laryngoscope to expose the vocal cords. The laryngoscope is pulled back as the rigid bronchoscope is advanced below the epiglottis and into the trachea.

Once the bronchoscope is passed into the trachea, the central airways can be visualized including the trachea, mainstem
Section I: General Thoracic Surgery

Fig. 1.16. Patient positioning for rigid bronchoscopy. The inset shows the view once the bronchoscope is passed beyond the tongue into the posterior pharynx.

bronchi, and lobar bronchi. At the carina, the patient’s head is rotated in the opposite direction to the side of the mainstem bronchus to be intubated, that is, to the left for the RMSB, and vice versa. The segmental bronchi are difficult to evaluate unless an angled telescope or a flexible bronchoscope is used through the rigid bronchoscope.

Esophagoscopy

When flexible esophagoscopy is performed under conscious sedation, the patient is placed in the left lateral decubitus position and the endoscopist stands facing the patient. When done under general anesthesia, the patient is intubated and placed supine while the endoscopist stands to the right side of the head. A gentle C-shaped curve is made at the tip of the scope, which is then passed over the tongue and under direct vision into the esophagus. The scope is inserted into the oropharynx and advanced through the pyriform sinuses into the esophageal lumen.

Using gentle insufflations to distend the esophageal lumen, the scope is advanced through the entire length of the esophagus and into the stomach. Care is taken to avoid passing the scope if any resistance is encountered. Even minimal force can cause disruption of the thin-walled esophagus. The inspection and assessment of the mucosa for pathologist done upon withdrawing the endoscope while the focus should be on the safe passage of the instrument during its insertion.

Once in the stomach, a retroflexion maneuver is performed in order to adequately inspect the cardia and the gastroesophageal junction. This identifies the presence of a sliding hiatal hernia or the extension of a tumor into the stomach. Photo documentation should be performed for any findings.

Rigid Esophagoscopy

Although occasionally performed by some under conscious sedation, the procedure is usually done under general anesthesia generally to provide better relaxation and lower the risk of perforation. The patient is positioned supine with the neck extended. The esophagoscope is introduced into the right side of the mouth and stabilized using the left thumb and forefinger as a fulcrum. It is advanced behind the right arytenoid cartilage into the right pyriform fossa. The head of the bed is lowered as the scope is advanced past the cricopharyngeus. Lowering the head further allows the scope to pass through the gastroesophageal junction by directing to the right side at the distal esophagus. Full examination is done on withdrawal to avoid missing any pathology under folded mucosa during advancement of the scope.

Any post-procedural chest pain should be considered related to an esophageal perforation until proven otherwise. This should be evaluated with an immediate esophagogram first with water-soluble contrast followed by dilute barium if no extravasation is seen with the water-soluble material.

TECHNOLOGICAL ADVANCES IN ENDOSCOPY

Since the introduction of fiberoptic endoscopy, several other enhancements have been developed to improve the yield of standard endoscopy including EUS, electromagnetic navigation bronchoscopy (ENB) and the use of different wavelengths for light.

Endosonography is the usage of special flexible endoscopes fitted with an ultrasound scanner at the tip that provide both an endoscopic and sonographic image. The images obtained are fed to a processor that can control settings such as gain, Doppler, and so on. Both esophageal and endobronchial endoscopes (Figs. 1.17 and 1.18) have been developed for this purpose. The endobronchial ultrasound (EBUS) scope has a convex probe while for esophageal EUS, scopes are available with both radial and linear probes. Both scopes utilize a saline-inflatable balloon at the tip to be inflated when direct probe to wall cannot be accomplished. For EUS, the radial probe provides axial images while the linear probe provides longitudinal ones. The endoscopic view from these scopes is at an angle. It is therefore important for the endoscopist to know that to obtain normal endoscopic straight view, the scope must be flexed toward the wall. Inexperience with this technique may result in accidental injury.

Once the scope is at the location of interest, the balloon may be inflated to maximize acoustic coupling to the wall. Lymph nodes are visualized and nodal size, station, and sonographic characteristics are recorded prior to biopsy. It is helpful to have any prior computer tomography (CT) scan or positron emission tomography scan imaging available
in order to correlate imaging findings with the procedural findings. The tip of the scope is gently flexed and pushed against the wall, aiming to maximize the observed diameter of the lymph node on the monitor. A 21- or 22-gauge needle is advanced under direct vision into the node. The stylet is then removed and the needle passed several times into the substance of the node. This material is then processed onto slides and into cell preservant for rapid onsite cytologic exam and cell block studies. During this procedure, a thorough knowledge of the surrounding vascular landmarks is essential. The Doppler function can confirm these structures.

The EUS scope can readily access mediastinal nodes at stations 1, 2L, 4L, 7, 8L, 8R, 9L, and 9R in addition to the left adrenal gland. EBUS can access 1, 2R, 21L, 4R, 4L, 7, 10R, 10L, and 11. It is obvious that EUS and EBUS should, therefore, be viewed as complimentary as the ability to combine both techniques in one setting can provide access to all the mediastinal stations except for the para-aortic and aortopulmonary window (stations 5 and 6).

The diagnostic power of flexible bronchoscopy is limited by its inability to guide biopsy instruments directly to certain lesions that are either extramural (e.g., mediastinal lymph nodes) or are too peripheral in the lung. In fact, the diagnostic yield of flexible bronchoscopy ranges from 36% to 84%, depending on the size and location of the lesion.

ENB (Fig. 1.19) provides a system to guide the bronchoscope to a specific point within the airway. The first part of this system is the three-dimensional reconstruction of axial CT scan images using specific software that also reconstructs the bronchial anatomy (virtual bronchoscopy). The second part of the system is a steerable probe that has a position sensor and is navigated through the airway that feeds its location to an electromagnetic field generator located on a board beneath the patient. The exact position of the probe is then correlated to the reconstructed images, allowing the ability to guide the bronchoscope and its instruments to the desired location. Possible applications for this system include needle biopsy of a peripheral lung lesion, the ability to place fiducials for stereotactic radiation, and the ability to inject a dye marker at the pleural surface of a lung nodule to facilitate finding it at the time of surgery.

Another technological addition to endoscopy has been the introduction of light with different wavelengths. This helps differentiate normal from pathological mucosa, which may both appear similar under standard white light endoscopy. A biopsy forceps can then be better directed at the tissue most likely to yield the abnormality. One example is autofluorescence bronchoscopy that utilizes ultraviolet light at 440 nm to inspect the mucosa. Normal mucosa fluoresces green, while mucosa from dysplasia or carcinoma appears pink.

Another modality is narrow band imaging in which the light of specific wavelengths (blue at 440 to 460 nm and green at 540 to 560 nm) is also used to inspect the surface of the mucosa. A special filter is electronically activated by a switch in the endoscope. Blood vessels appear dark and distinct, resulting in increased contrast between the epithelial surface and the underlying vascular network. This can help differentiate abnormal, hypervascular epithelium from the surrounding normal lining.

**CONCLUSION**

The ability to perform accurate thoracic endoscopy is essential for appropriate evaluation of thoracic disease. This is an area where formal training is provided by different specialties and to varying degrees depending on the specific interests of the center. The vast technological advances in this field have made it more challenging to acquire the necessary skills to become proficient at these modalities. Despite this, it is still important for the thoracic surgeon to become both familiar and facile at all aspects of thoracic endoscopy. Even when a patient has had a previous endoscopy, it is invaluable for the surgeon to visualize the pathology to allow for better planning of the approach for the operative procedure. Furthermore, many of these endoscopic procedures such as endoscopic stenting may be necessary adjuncts to patient care.
Fig. 1.19. (A) Electromagnetic navigation bronchoscopy (ENB) unit (with permission from iLogic). (B) ENB Navigation Screen. After loading the reconstructed CT scan data, a virtual bronchoscopy is obtained. The computer-generated pathway to reach the target lesion in the left lower lobe is shown. The endoscopist follows this pathway that can be seen in different views including virtual bronchoscopy, three-dimensional view, and CT views. (C) Fluoroscopy aids in performing the biopsy safely and accurately.
This is a superb chapter that nicely summarizes both the old and the new of thoracic endoscopy. As the author mentions, endoscopy is now shared among a number of specialties but it remains incumbent on the thoracic surgeon to not only be familiar with the techniques but be expert at performing them. The threat of losing this expertise looms if thoracic surgeons become too comfortable at letting others perform the endoscopic procedure and simply depend on a report. This is not to say that our medical colleagues are not expert at performing endoscopic procedures, it is simply to say that optimal planning of a surgical procedure often requires the surgeon to visualize the anatomy and the pathology. The perspective of the surgeon differs from that of the medical endoscopist though both should work closely for the benefit of the patient.

I feel it is necessary to comment on the status of rigid endoscopy, procedures that may become a lost art. To me it is absolutely necessary for a thoracic surgeon to be facile with rigid bronchoscopy as the need surely will arise for the emergency establishment of an airway whether obstructed by tumor or foreign body. There are just situations where flexible bronchoscopy is not the procedure of choice. The ability to work through a large working channel while being able to ventilate the patient through the same instrument provides significant advantages at times. The thoracic surgeon should be able to place a rigid bronchoscope using only the scope itself to visualize and lift the epiglottis to expose the vocal cords and safely pass the instrument into the trachea. This can be a life-saving procedure. I am afraid that we are not doing a great job of exposing current thoracic surgical residents to enough rigid bronchoscopies for them to become expert and there is a potential for patients to suffer. The ease with which flexible bronchoscopy may be done has, in many situations but not all, obviated the need for rigid instrumentation. But in certain situations, there is no substitute for the rigid endoscope.

Rigid esophagoscopy, I fear, is a dying art that is not being taught. Passing the rigid esophagoscope can be fraught with danger specifically of perforation if not done with perfect technique. The area of the cervical prominence at C7 is the area most commonly perforated if the instrument is not lifted up and away from that area as it is passed. The lumen must be visualized at all times. Choosing the appropriate length of instrument based on the procedure to be accomplished is also critical. If only the upper esophagus needs to be evaluated with the rigid instrument, a shorter scope that is easier to manage may be utilized. It goes without saying that managing esophageal strictures is greatly facilitated at times with the use of the rigid instrumentation but our gastroenterology colleagues, who are not trained in the use of these, use the flexible endoscopes and seemingly dominate these procedures in the current era. In a way, it is sad that current thoracic surgical trainees may have to forego the management of patients with esophageal strictures or the palliative management of esophageal tumors as the gastroenterologists have claimed much of this work. Hopefully, thoracic surgical education will continue to include EUS and EBUS so we do not cede these procedures completely to our medical colleagues but work collaboratively with them.

LRK
INTRODUCTION

Lung cancer staging is continuously evolving as technological advances improve the imaging and endoscopic modalities available to better stratify patients into treatment and prognostic categories. The benefits of enhanced staging modalities, both local and metastatic, are to enrich the population of patients who can benefit from surgery and to avoid surgery in those patients who are not likely to benefit. The tumor-node-metastasis (TNM) staging system for lung cancer has undergone multiple revisions since 1986 when it was first published by Clifton Mountain based on 2155 lung cancer patients derived from a single institution, University of Texas, MD Anderson Cancer Center. The current seventh edition staging system for lung cancer (revised in 2009, and summarized in Tables 2.1 and 2.2) has been validated in a data set of 81,015 lung cancer patients from 19 countries, but excludes some patient populations in Africa, South America, the Indian subcontinent, and parts of China. It is the basis on which treatment strategies are constructed and is highly dependent upon accurate staging.

Operative intervention is routinely offered for stage I (lymph node negative, T1a, T1b, N0, and T2a) and stage II (T1c, T2b, N0, T2a, N1, T2b, N0, T3, N0) patients. Complete resection in stage I yields a cure rate of ~58% to 73% and is not enhanced by adjuvant regimens except in a subset of stage IB tumors >4 cm. Recent evidence seems to support a survival advantage for adjuvant therapy in resected stage II and III disease. Node-negative superior sulcus tumors stage IIB (T3, N0, or T4, N0) tumors that can be resected en bloc are best treated surgically, with selective use of concurrent chemotherapy and external beam radiation given preoperatively. Stage IIIA disease (T3, N1, or T4, N1) is a heterogeneous group of locally advanced tumors where multimodality therapy including surgery should be carefully considered. At the other end of the spectrum, stage IIIB and IV patients, with rare exceptions, do not benefit from surgical resection. A subset of stage IV patients with oligometastatic disease of solid organs (such as brain and adrenal gland) and no N2 disease may benefit from resection of the metastatic site and lung to achieve a 5-year survival approaching 20%.

Techniques for the identification and subsequent staging of lung cancer have improved; however, no single modality has been able to noninvasively confirm definitively the presence of lymph node metastases. Computed tomography (CT), positron emission tomography (PET), and less frequently routine magnetic resonance imaging (MRI) of the chest have been employed as clinical staging modalities for lung cancer. Lung cancer staging should include a diagnostic quality CT, a PET to evaluate the mediastinal lymph nodes and exclude extrathoracic or bone metastases, and liberal use of more invasive types of mediastinal staging such as, mediastinoscopy, endobronchial ultrasound (EBUS), and/or esophageal ultrasound-guided fine needle aspiration (EUS-FNA) of lymph nodes, and in selected patients video-assisted thoracoscopy (VATS). All of these modalities have different sensitivity and specificity for lymph node staging. Lymph node metastasis portends a worse prognosis, and surgical resectability for cure is greatly influenced by mediastinal lymph node involvement.

Evaluation of mediastinal lymph node metastases by CT alone has been extensively reviewed in the literature and has historically yielded an overall sensitivity of 59% (range 20% to 81%) and an overall specificity of 78% (range 44% to 100%). PET evaluation of the mediastinum for stage I and II non-small cell lung cancer (NSCLC) has yielded a sensitivity of 85% and specificity of 88%. Its negative predictive value for the mediastinum is 87%, whereas the positive predictive value is 56%. Specificity of PET is limited as both neoplastic and inflammatory nodes can have increased fluorine-18-labeled deoxyglucose (FDG) uptake. Meta-analysis of 44 relevant studies that explored the diagnostic accuracy of PET compared with CT imaging in detecting mediastinal lymph node metastases demonstrated that PET was more accurate. Accurate detection of hilar nodal involvement in lung cancer has historically been difficult, but with CT-PET and more widespread use of EBUS transbronchial needle aspiration biopsy, pathologic correlation has proven that PET is very good at detecting N1 disease.

The widespread use and availability of PET-CT fusion imaging has increased the proportion of patients found to have additional lesions that contraindicate surgical treatment but require tissue confirmation to exclude a false-positive examination. For optimal results from PET-CT, patients fast for 4 to 6 hours and then receive 15 mcs of 18-FDG (550 MBq) as an intravenous injection 1 hour before study. 18-FDG has a 110-minute half-life. Transmission CT (5 mm cuts) is acquired during quiet breathing and then the PET evaluation is acquired. CT-PET acquisition takes about 30 to 35 minutes. Importantly, the transmission CT scan that is generated by this modality is not as accurate as a diagnostic quality CT chest. This technology has been evaluated in the literature with increasing frequency. In a sentinel study from Switzerland in 2003, the authors studied PET-CT in 50 patients with NSCLC. Integrated PET-CT provided additional information in 41% of patients and was significantly more accurate in precise staging compared with CT alone, PET alone, or visual correlation of PET and CT.

MRI of the lung has historically been challenged by poor spatial resolution and high noise-to-contrast ratio and has been reserved for characterizing mediastinal masses or detecting tumor invasion into chest wall, mediastinum, vasculature structures, diaphragm, pericardium, or bone. MRI has greatly contributed to the clinical staging of superior sulcus tumors. A recent report suggests that new MRI techniques such as diffusion-weighted imaging (DWI)

and short tau inversion recovery turbo spin echo (STIR) sequences can improve upon the accuracy of PET/CT for distinguishing benign from malignant lymph nodes. Furthermore, PET-MRI is the newest modality that is being evaluated for lung cancer staging.

**MEDIASTINOSCOPY**

The gold standard for staging the mediastinum is cervical mediastinoscopy, which was developed by Harken and associates in 1954 and then promulgated by Carlens in 1959 and later Pearson in 1965. Carlens and Pearson recognized that mediastinoscopy potentially was useful not only for lung cancer staging but also for the diagnosis of lymphoma, metastatic disease from an extrathoracic origin, infectious etiologies, and sarcoidosis. It is the benchmark against which all comparisons of lymph node accuracy are currently analyzed. The mediastinoscopes used today are modifications of the original instruments, with distal illumination, a beveled end, and a lateral slit for instrumentation (see Fig. 2.1). The efficacy of mediastinoscopy has been well established in the assessment of enlarged mediastinal lymph nodes with 100% specificity and ~90% sensitivity. In patients with known or suspected lung cancer, the routine use of mediastinoscopy can change the plan of care in up to 25% of patients. Large studies confirm false-negative rates from 5% to 8%, as demonstrated in Table 2.3. The false-negative rate of mediastinoscopy may be attributed to the diligence of the surgeon dissecting and sampling the nodes. Ideally, five nodal stations (stations 2R, 4R, 7, 2L, and 4L) should be routinely examined (see Fig. 2.2), with at least one
node sampled from each station unless none are present after dissection in the region of a particular nodal station. Compared with conventional mediastinoscopy, video mediastinoscopy appears to yield some improvement in sensitivity (92%) and false-negative rates (7%).

Routine mediastinoscopy remains somewhat controversial in that many lung cancer treatment centers use the modality selectively. A national survey of 729 hospitals (31% teaching or university hospitals, 38% community cancer centers, 46% comprehensive community cancer centers) sponsored by the American College of Surgeons identified more than 11,668 patients whose initial management included surgical therapy for lung cancer.

The mediastinum was evaluated preoperatively with mediastinoscopy in only 27% of these surgical patients and only 26% underwent a staging PET. The underuse of aggressive mediastinal staging in both academic and community lung cancer care is sobering. Additionally troublesome is that only 42% had lymph nodes sampled at any mediastinal level during the definitive surgical procedure.

### Indications and Contraindications

Mediastinoscopy should be performed in any patient harboring a suspicious lung nodule with enlarged (>1 cm in short axis measured on CT) or FDG-avid mediastinal lymph nodes (N2 or N3), those with central tumors, and those with peripheral tumors >2 cm. T1 tumors with an aggressive histology (i.e., large cell neuroendocrine carcinoma, small cell or pleomorphic carcinomas) should also undergo mediastinoscopy. Peripheral T1a lesions (tumors ≤2 cm) with PET-negative mediastinal lymph nodes can be regarded as the one exception to the routine use of mediastinoscopy. Mediastinoscopy is the procedure of choice for lung cancer staging (endorsed by the American College of Chest Physicians, and European Society of Thoracic Surgeons) but endoscopic techniques such as EBUS or EUS-FNA are recognized as modalities where a cytologic diagnosis can be achieved to initiate a treatment strategy. If EBUS or EUS-directed biopsies are negative in a pathologically enlarged or FDG-avid mediastinal lymph node, mediastinoscopy is still recommended.

Mediastinoscopy does not have many strict contraindications except for perhaps inability to extend the neck because of severe kyphosis or fused cervical vertebra. Relative contraindications to mediastinoscopy include large thyroid goiter, severe atherosclerotic disease in the aortic arch, vertebral arteries (vulnerability to ischemic events with neck extension), or the innominate artery which can contribute to embolic stroke. End tracheal stoma after laryngectomy in association with neck radiation can present anatomic difficulty with increased risk of cervical wound infection. Previous mediastinoscopy is associated with fibrosis of the pretracheal tissue plane and makes redo mediastinoscopy challenging. Despite this phenomenon, repeat mediastinoscopy is feasible and safe in most cases and can be carefully used to restage the mediastinum after induction therapy. Particular care must be exercised in separating the

**Fig. 2.2.** The Mountain-Dresler modification of the regional lymph node map originally proposed by the American Thoracic Society. (Redrawn after Mountain CF, Dresler CM. Regionally lymph node classification for lung cancer staging. Chest 1997;111:1718-1723c.)
innominate artery from the trachea. Sharp dissection under direct vision is safer than the blunt approach used in first-time mediastinoscopy. Many surgeons reserve EBUS-directed biopsy for preinduction mediastinal lymph node sampling in patients suspected of harboring locally advanced lung cancer (stage IIIA) with positive N2 nodes.

**Technique**

Mediastinoscopy is an outpatient procedure that needs to be performed in a hospital setting to efficiently manage the potential for hemorrhage. The patient is placed supine on the operating room table where the head is placed at the top of the bed (Fig. 2.3). After establishing general endotracheal anesthesia, the neck is extended with either a thyroid bag or a roll under the shoulders. A pulse oximeter or radial artery cannula can be used to monitor compression of the innominate artery (observation of a dampened waveform) so as not to compromise blood flow to the right carotid artery for an extended period. Most surgeons include the entire sternum in the operative field in the event that serious hemorrhage is encountered and median sternotomy is necessary. In the event that a patient already has a previous median sternotomy, a right or left anterior thoracotomy can be considered for exploration in the setting of acute hemorrhage. Mediastinoscopy can be achieved with direct visualization through a standard scope (Fig. 2.1) or via a magnified view with a video mediastinoscope (Fig. 2.4). Video mediastinoscopy permits both direct and monitor viewing and facilitates teaching since all participants in the operating theater can observe. As previously mentioned, video mediastinoscopy has been shown to improve lymph node sampling over conventional mediastinoscopy.

Dissection is carried down through the incised platysma muscle to the strap muscles (sternothyroid and sternohyoid). The thyroid isthmus is rarely divided. Palpation of the trachea helps identify the soft tissue midline where the strap muscles (see Fig. 2.5) can be vertically separated to allow sharp entry into the pretracheal alveolar plane. There is often an adipose layer in the midline. The anterior tracheal wall is visualized (Fig. 2.5C) and a tunnel can be created by bluntly spreading with a Metzenbaum scissors or by insertion of the index finger. Blunt finger dissection caudally (Fig. 2.6) can often permit palpation of the innominate artery pulse which later can be vulnerable to compression when using the mediastinoscope. Finger dissection is continued down the trachea where the surgeon can appreciate tissue resistance and texture of mediastinal lymph nodes (Fig. 2.7). It is essential to assess the area just above the sternal notch early in the dissection because neck extension may elevate the innominate artery up into the base of the neck where it can be injured by sharp dissection or cautery.

The mediastinoscope can be inserted into the pretracheal tunnel where a suction cautery dissector is used to bluntly dissect this alveolar plane with occasional fibrous bands (Figs. 2.8 and 2.9). The instrument is advanced only if it passes easily and there is a visible tunnel ahead. The surgeon can explore the entire length of the trachea and both main stem bronchi. The landscape is carefully surveyed to identify lymph nodes in the various stations depicted in Figure 2.10. Nodes are identified by color and consistency. Particular care is taken when
retrieving specimens near the tracheobronchial angles because of the proximity of the azygos vein and apical branch of the truncus anterior pulmonary artery on the right and the recurrent laryngeal nerve on the left. The right main pulmonary artery is observed superior to the carina and can be injured with cautery while achieving hemostasis from biopsies of subcarinal lymph nodes. All dissection and lymph node biopsies should be in close proximity to the airway. The blue-gray hue of venous structures can sometimes be mistaken for an anthracotic node. If there is any doubt about the solid or vascular nature of the tissue in question, aspiration is performed using a 20- or 22-gauge spinal needle and 10 to 20 cc syringe (Fig. 2.11). Target lymph nodes should be partially dissected before any biopsy specimens are taken to reduce bleeding. Once sufficiently freed, the node is grasped with a cupped biopsy forceps, and traction is applied under direct vision (Fig. 2.11C). If the node cannot be extracted by gentle pulling and twisting, further dissection is carried out or an additional instrument can be introduced down the scope to divide tethering attachments or stabilize the origin of the lymph node to avoid traction injury to adjacent vasculature. The goal of standard mediastinoscopy is to sample lymph nodes and not perform lymphadenectomy. When sampling lymph nodes for lung cancer, it is important to sample multiple lymph node stations. Samples are routinely obtained from stations 2, 4, and 7 (see Fig. 2.10). Of note, station 10 is a hilar node (N1) and by definition resides inside the pleural envelope and cannot routinely be accessed with standard mediastinoscopy techniques. EBUS is the modality of choice for accessing this nodal station. Sampling nodes contralateral to the primary tumor is paramount to identify patients who harbor N3 disease (stage IIIB) where definitive surgical resection would be contraindicated most of the time. Labeling all specimens by numerical station is less subject to error and removes ambiguity from pathology reports. This behavior should be aggressively embraced when training since it improves communication (common language among all treating physicians) and provides more accurate data when performing clinical research.

Complications
The incidence of complications for mediastinoscopy across large series is extremely low (summarized in Table 2.4). Although catastrophic hemorrhage can occur during mediastinoscopy, most bleeding is minor and can be controlled with application of Surgicel (oxidized cellulose), transient packing, or partial withdrawal of the scope to tamponade the mediastinum. Occasionally hemoclips can be used in the face of a visible small vessel particularly in the subcarinal area where bronchial arteries are prevalent. Cautery should not be used anywhere along the left paratracheal space to avoid thermal injury to the recurrent laryngeal nerve. If significant bleeding occurs, the mediastinum is packed and left in place for at least 10 minutes and then gently removed. Blood for transfusion should be made available in the operating theater along with additional instruments. If hemorrhage continues, packing is reinstituted, and median sternotomy or thoracotomy is emergently performed. Median sternotomy is the most versatile incision and preferred for hemodynamic instability, or injury to innominate artery, aortic arch, or right pulmonary artery. It also allows better access for cardiopulmonary bypass if necessary to control hemorrhage from a major vessel. Performing pulmonary resection after control of major bleeding is

Fig. 2.5. Mediastinoscopy: small cervical neck incision (A) just about the sternal notch. After division of platysma muscle, strap muscles are exposed to identify the midline (B). Pretracheal fascia is sharply divided and raised to expose trachea (C).
A disadvantage of median sternotomy. Right thoracotomy is often employed for the more common azygos vein injury and for the less common superior vena caval injury. Large studies confirm low morbidity and mortality as described in Table 2.3. The most underreported complication from mediastinoscopy is left vocal cord paralysis from recurrent nerve injury, observed with traction injury from the scope as well as thermal injury from cautery. Esophageal injury is extremely uncommon and can be encountered in association with aggressive biopsy at the low left paratracheal or subcarinal space. This injury may not be immediately recognized and the patient may present postoperatively with mediastinal air, mediastinitis, or pleural effusion. Esophagram should be obtained and the injury managed with techniques similar to those for managing other traumatic injuries to the esophagus. Pneumothorax can be observed when violating the parietal pleura and is not often associated with a parenchymal injury. This can be managed intraoperatively using a flexible rubber catheter that is brought out through the cervical wound. After the mediastinoscope is removed, pleural air is evacuated during a Valsalva maneuver as the tube is removed. If there is a recognized lung parenchymal injury, tube thoracostomy must be performed.

Extended Cervical Mediastinoscopy

Extended cervical mediastinoscopy is a modality that is performed only by few thoracic surgeons and therefore is not routinely part of thoracic surgery education. It was designed to stage patients with left upper lobe lung cancers in whom standard cervical mediastinoscopy results are negative. Ginsberg and colleagues devised a method for access to the paraaortic (station 6) and aortopulmonary (station 5) lymph nodes. The approach originates through a standard cervical incision where a tunnel is created over the aortic arch, between the innominate artery and the left carotid artery (see Fig. 2.12). The mediastinoscope is inserted obliquely to reach the subaortic space. The distinction between the subaortic and para-aortic space is difficult and frequently limited by the bony chest wall. In addition to potential injury to the innominate and carotid artery, injury can be observed to the left main pulmonary artery, left recurrent laryngeal nerve, and left phrenic nerve. Alternatively, these nodal stations can be accessed by anterior mediastinotomy or VATS with improved visualization.

Anterior Mediastinotomy/ Mediastinoscopy

This procedure was described in 1966 by McNeill and Chamberlain and is often employed in lieu of extended cervical mediastinoscopy for lung cancer staging. It is an outpatient procedure that can target enlarged prevascular (station 6) or aortopulmonary (station 5) lymph nodes in the setting of lung cancer or anterior mediastinal masses that require a diagnosis. When mediastinotomy is indicated by CT findings, it is usually preceded by mediastinoscopy in the setting of lung cancer staging. The procedure requires general anesthesia and a single-lumen endotracheal tube. It can be performed through a 5-cm transverse incision at the left sternal border over the second or third interspace. The fibers of the pectoralis muscle are split to expose the cartilage. Although the original description recommends excision of the second costal cartilage (Fig. 2.13), this can be obviated with the use of a mediastinoscope (Fig. 2.14). The mediastinum is entered after incising the endothoracic fascia. The internal mammary artery and vein may be ligated if necessary but can often be retracted and preserved (Fig. 2.13C). Although an extra-pleural plane can be developed to access station 5 or 6, this is not always feasible. When sampling a mediastinal mass suspicious for a thymic neoplasm, entering the pleural space can be a risk for pleural dissemination of disease and should be avoided if possible. The mediastinotomy site is often excised (full thickness) during
definitive surgical management of thymic neoplasms to reduce the incidence of local tumor recurrence by virtue of tumor cell implantation at the time of mediastinotomy. When mediastinotomy is done in conjunction with cervical mediastinoscopy, the neck incision is left open to allow bidirectional palpation of the aortopulmonary region (Fig. 2.15). A mediastinoscope is useful for improved lighting when performing biopsy with a cup forceps. If the pleural cavity is entered, one can aspirate the pneumothorax using a flexible rubber catheter that is brought out through the wound edge. After wound closure, pleural air is evacuated during a Valsalva maneuver as the tube is removed. Potential pitfalls here are inadvertent biopsy of the left main pulmonary artery or aortic arch or injury to phrenic or recurrent laryngeal nerve. Chylothorax after mediastinotomy is rare, but has been reported. Adequate visualization is mandatory and if it cannot be achieved, thoracoscopy can be added through additional port incisions while intermittent ventilation is employed.

**OTHER STAGING MODALITIES**

**Supraclavicular (Scalene) Lymph Node Biopsy**

Supraclavicular lymph node biopsy is currently reserved for palpable disease in the setting of lung cancer or other disease processes such as lymphoma, metastatic disease from an extrathoracic site, sarcoidosis, or infectious disease. Enlarged lymph nodes in this region may be amenable to needle aspiration, but a negative aspirate in an enlarged lymph node does not rule out disease. Excisional biopsy is preferred for enlarged lymph nodes where a formal excision of the scalene fat pad is less utilized. Historically, scalene fat pad excision was the mainstay of nodal staging in lung cancer before the advent of mediastinoscopy. The positivity rate in the absence of palpable adenopathy varied from 3% to 20%, with central adenocarcinomas having the highest incidence. Excisional or incisional biopsy of a supraclavicular lymph node can be the first diagnostic procedure in patients who present with suspicious lung mass and enlarged neck nodes. Confirmation of node-positive disease with this technique invokes at least pathologic TxN3 lung carcinoma (stage IIIb). Pitfalls in executing this procedure are injury to the phrenic nerve, chyle leak when dissecting in the left supraclavicular fossa, and bleeding.

**Esophageal Ultrasound**

EUS-FNA is a minimally invasive alternative technique for mediastinal staging of NSCLC. The concept was introduced in 1996. Access to all mediastinal nodes is limited to left paratracheal (stations 2L and 4L), subcarinal (station 7), paraesophageal (station 8), and inferior pulmonary ligament (station 9) lymph nodes (depicted in Fig. 2.10). EUS can visualize stations 5 and 6 lymph nodes, but the feasibility of needle biopsy is limited to the inferior aspect of station 5 with favorable anatomy. Advanced users have described a method to sample the para-aortic (station 6) lymph node without traversing the aorta. EUS can also detect and sample metastatic (M1) disease in the adrenal glands and liver. Aside from thoracoscopy or thoracotomy, EUS is the only modality that can access N2 lymph nodes along the esophagus and inferior pulmonary ligament (stations 8 and 9). EUS-FNA has been shown to be highly accurate in detecting mediastinal lymph node metastases with an overall diagnostic yield of 90% and a false-negative rate of 22%. Because of the insufficient negative predictive value, negative results with EUS-FNA in an enlarged lymph node should be verified by surgical staging. A meta-analysis was performed to estimate the diagnostic accuracy of EUS-FNA for staging mediastinal lymph nodes (N2/N3...

Fig. 2.9. Video mediastinoscope with suction cautery. (Obtained from Video mediastinoscopy copyright 2011 Endo Press Tuttlingen, Germany.)
Endobronchial Ultrasound

There is mounting data regarding the use of EBUS and staging of lung cancer. The modality was originally applied to lung cancer staging by Yasufuku and colleagues in 2004. Real-time EBUS transbronchial needle aspiration (TBNA) is highly accurate and safe for sampling enlarged mediastinal lymph nodes. Integrated color power Doppler ultrasound is used to avoid intervening vessels immediately before needle puncture. EBUS can be performed in an outpatient setting with either conscious sedation or general anesthesia. Biopsies can be performed using a 21- or 22-gauge needle with a maximal extension of 40 mm (Fig. 2.15). Fine needle aspiration is performed by passing a needle through the tracheal or bronchial wall into adjacent lymph nodes or central or perihilar parenchymal masses under real-time ultrasound control (Fig. 2.16). Specimens can be smeared on glass and fixed with ethanol or sprayed with Cytofix. Additional specimens can be placed in 10% formalin or saline in preparation of a cell block to perform immunohistochemistry. Of great importance in the contemporary treatment of lung cancer, this small amount of tissue can be used for molecular genotyping (i.e., EGFR, ALK, ROS1, BRAF, HER2, and others) to identify patients who will benefit from targeted therapy, or be eligible for clinical trials, particularly in the setting of metastatic disease.

Compared with mediastinoscopy, EBUS-TBNA has the advantage that it is also able to routinely access posterior mediastinal (station 7) and hilar lymph nodes (stations 10, 11, and 12) in addition to bilateral paratracheal nodes (stations 2 and 4). Figure 2.10 shows the extent of accessible lymph nodes when using EBUS. A recent study by Herth and colleagues suggests that patients with a normal CT and PET of the mediastinum can be primarily evaluated and staged during a diagnostic bronchoscopy with EBUS-TBNA of all nodes larger than 5 mm, especially if the primary tumor is known to be an adenocarcinoma. Unfortunately, champions of the procedure tend to have better results than those obtained by all other users. The false-negative rate of EBUS has been reported to be 15% to 28%. A meta-analysis of EBUS in lung cancer staging reviewed 365 publications where only 10 were suitable for analysis. EBUS-TBNA biopsy had a pooled sensitivity of 88% (range 80% to 94%) and a specificity of nearly 100% (range 92% to 100%).

To date there have been two randomized controlled clinical trials comparing mediastinal nodal surgical staging (mediastinoscopy) of lung cancer to combined EBUS-TBNA and EUS-FNA. The trials enrolled over 100 patients per study arm and were designed to implement mediastinoscopy as a follow-up modality to the EBUS/EUS arm if no nodal metastases were detected on needle aspiration biopsy.
Chapter 2: Mediastinoscopy and Other Thoracic Staging Procedures

Fig. 2.11. The circle depicts the right tracheobronchial angle (station 4R). Tissue is identified and aspirated with a needle to ensure the absence of a vascular structure (A). An edge of lymph node is dissected free (B) and biopsied with a cup forceps (C).

Fig. 2.12. Extended cervical mediastinoscopy: tunnel over the aortic arch is created (A) to reach the aortopulmonary window with the standard mediastinoscope (B).
In both of these randomized studies thoracotomy with lymph node dissection was performed when there was no evidence of mediastinal tumor spread. Both studies demonstrated that the endosonographic modalities (EBUS/EUS) and mediastinoscopy were complementary and not mutually exclusive in the comprehensive evaluation of mediastinal lymph nodes. Endosonography (followed by surgical staging if negative) resulted in greater sensitivity and improved negative predictive values for mediastinal nodal metastases and fewer unnecessary thoracotomies. EBUS can be used for nodal staging of lung cancer, restaging the mediastinum after neoadjuvant therapy, assessment of isolated hilar or mediastinal lymphadenopathy, and sampling of perihilar parenchymal masses. The American College of Chest Physicians recommends 50 supervised procedures to achieve proficiency; however, there is evidence to suggest that thoracic surgeons can achieve proficiency after 10 supervised procedures.

EBUS is also highly sensitive and cost effective for isolated mediastinal lymph node enlargement in diseases other than lung cancer including both benign and malignant disease (sarcoidosis, metastatic disease from extrathoracic sites, and even lymphoma). The sensitivity and negative predictive value of EBUS-TBNA in patients with isolated mediastinal lymph node enlargement is 92% and 40%, respectively.

**Video-Assisted Thoracoscopy**

VATS is another powerful modality in the armamentarium of thoracic surgeons for improving pathologic staging of locally
advanced lung cancer. It is frequently used at the time of pulmonary resection to rule out pleural metastases and more accurately assess T stage, particularly when the tumor abuts the chest wall, vascular, or mediastinal structures. VATS can also be used to assess enlarged pre-vascular (station 6) and aortopulmonary (station 5) lymph nodes in the setting of a left upper lobe NSCLC. More is discussed about this technique in another chapter.

CONCLUSION

All of these modalities must be included in the modern education of a thoracic surgeon including the endoscopic techniques of EBUS and EUS for mediastinal lymph node sampling. Each of these modalities is complementary and can be performed in an orderly sequence during a single general anesthesia.

SUGGESTED READINGS

Fig. 2.17. Endobronchial ultrasound transbronchial needle aspiration (EBUS-TBNA) biopsy of subcarinal (level 7) mediastinal lymph node. (Origin Lanuti.)

As Dr. Lanuti points out, mediastinoscopy remains the definitive procedure for staging the mediastinum in patients with nonsmall cell lung cancer. In addition, it remains the benchmark against which all other mediastinal staging procedures are compared. Endoscopic bronchial ultrasound-guided biopsy clearly has added to the armamentarium of the thoracic surgeon and provides visual confirmation of the lymph node being sampled. However, a negative needle aspirate of an enlarged lymph node even when the node is sampled under ultrasound guidance should not be accepted truly as negative until a sample obtained at mediastinotomy confirms the finding. Not every patient requires separate mediastinal staging prior to resection, specifically if the fused CT/PET scan shows no enlarged lymph nodes and no increased uptake of radioisotope.

Mediastinoscopy is difficult to teach because it essentially is a single-operator procedure though the advent of the video mediastinoscope has made it somewhat easier. Part of the difficulty in teaching the procedure resides in the fact that the tactile sense is particularly important for optimal performance and that is difficult to convey even if the trainee can see what is being done on the video screen. The feel conveyed through the suction tip as it is used to dissect is critical to being able to distinguish lymph node from vessel. The azygous vein, for example, looks very similar to a lymph node, yet clearly there is a distinct difference in feel when the suction tip is pushed against it as compared to when touching the lymph node. The possibility of major vascular injury makes mediastinoscopy a formidable procedure that causes the inexperienced operator to be somewhat tentative in the exploration of the mediastinum. This tentativeness also results in many mediastinoscopies done where no nodal tissue is obtained, and this not only subjects a patient to needless risk but also does nothing to gain additional information that may be critical to establish the optimal treatment regimen.

As Lanuti points out, nodes at multiple levels should be sampled in order to obtain the maximum amount of information. However, one should avoid getting greedy during the procedure and recognize that the aim is not to perform a lymphadenectomy but to just obtain representative samples. Nodes from both the right and left side should be obtained specifically at levels 2 and 4 as well as a sample of the subcarinal (level 7) lymph node. When dissecting in the left paratracheal region, the left recurrent laryngeal nerve is at risk of injury and care must be taken when using the electrocautery. The left paratracheal nodes occur somewhat more cephalad than those on the right and pushing posteriorly with the tip of the mediastinoscope aids in identifying the left-sided nodes.

It should be kept in mind that it is okay to think when performing mediastinoscopy and not simply sample everything in sight. For instance, if a contralateral lymph node is suspected of being involved, tumor sampling of that node first may obviate the need for any further sampling if on frozen section the node proves to be positive. The disease at that point has been staged with the demonstration of N3 disease and further sampling to prove N2 disease is not only pointless but also subjects the patient to additional needless risk. If one is performing mediastinoscopy to assess enlarged lymph nodes in the absence of a primary lung cancer, the first demonstration of a pathologic lymph node on frozen section terminates the procedure.

The most common cause of bleeding during the procedure is not a major vessel injury but simply bleeding from a lymph node with the subcarinal space being the most common site. Use of electrocautery usually controls this but packing with a hemostatic agent such as oxidized cellulose may also be used. Intimate familiarity with the anatomy of the superior mediastinum gained by experience with the procedure usually serves to avoid major vessel injury but the azygous vein and the apical anterior branch of the right pulmonary artery are the vessels most at risk. Injury to the right main pulmonary artery or to the innominate artery is also possible though these structures are readily visible. The first indication of a major vessel injury occurs when the field of vision suddenly goes dark. The mediastinum should immediately be packed with gauze (vaginal packing serves this purpose well) and preparations made for a median sternotomy. After a waiting period of 10 minutes or so, the packing is moistened with saline and slowly removed. If bleeding has stopped, a further period of observation is warranted but if there is any doubt a median sternotomy should be performed and the vessel repaired. Continued bleeding after the pack is removed calls for repacking and immediate median sternotomy. Additional help should be summoned as well. Extended cervical mediastinoscopy is mentioned here only to be condemned, in my opinion. If access to the aortopulmonary window is desired either anterior mediastinotomy or video thoracoscopy should be the procedure of choice.

Anterior mediastinotomy provides access to the aortopulmonary window and may be accomplished in an extrapleural plane especially if a piece of the second costal cartilage is removed. One should keep in mind that level 5 (aortopulmonary lymph node) disease in the presence of node negativity in the rest of the mediastinum essentially behaves like N1 disease and whether it needs to be documented prior to resection is debatable. In my own practice, isolated level 5 disease is a straightforward surgical issue.

LRK
The optimal approach to the thorax depends on a number of variables including bony and hilar anatomy, location and extent of pathology, the objectives of the procedure, and the experience of the surgeon. Historically, the posterolateral thoracotomy was the workhorse for the majority of major thoracic procedures, the majority of approaches to thoracic pathology were performed through this, and there was significant short-term and long-term morbidity associated with the operations we performed. Today, with advances in surgical techniques, emphasis on less invasive procedures, optimization of perioperative care, and approaches to thoracic pathology have become more diverse and specialized. In addition to the prerequisite factors required for planning an approach, one may also consider alternative strategies for the management of lung isolation, positioning, and the inherent limitations of the instrumentation or the additional time required to complete a minimally invasive or multi-phased procedure.

Given the short-term morbidity as well as chronic pain associated with traditional approaches, alternative approaches are becoming routine. These approaches may favorably affect morbidity, operative time, postoperative pulmonary function, muscle strength, cost, and postoperative pain. Although the specific costs associated with a minimally invasive approach appear to be increased, these are offset by shortened time in intensive care units and decreased length of stay. In the future, less invasive, tissue-sparing approaches may also demonstrate additional benefits as it relates to oncologic outcomes. It is not clear if this is a benefit of the approach in relation to decreased tissue damage and decreased cytokine response versus improved recovery and a thus earlier initiation of adjuvant therapy. Given the limited access provided through these minimally invasive approaches, careful preoperative planning and operative steps and strategy should be routinely visualized prior to performing the operation. Anticipation of intraoperative steps and exposure will go a long way toward preventing misadventures during the surgical procedure.

**LUNG ISOLATION**

For traditional and minimally invasive approaches, lung isolation with a double-lumen endotracheal tube remains the key maneuver to facilitate working within the pleural cavity. Given the length of the left main stem bronchus, left-sided tubes are the preferred choice, except in the setting of a left-sided sleeve resection.

At times, lung isolation through a double-lumen tube may be unnecessary or problematic, as in patients with an endotracheal stoma. Alternative lung isolation strategies include placement of a bronchial blocker or direct compression of the lung with CO₂ insufflation. When using a bronchial blocker, it is important to instruct the anesthesiologist to deflate the bronchial balloon and disconnect the ventilator. This will allow the ipsilateral lung to collapse more readily releasing any air that might be trapped behind the balloon.

Visualization within the pleural space may be facilitated with CO₂ insufflation if a single-lumen endotracheal tube must be used. In this setting, unlike that of laparoscopic surgery, a pressure of 10 mmHg is sufficient to collapse the lung and obtain a working space. Pressures >10 mmHg are often poorly tolerated due to the creation of tension physiology. Lesions accessible with this type of approach are simple wedge resections, as well as anterior and posterior mediastinal lesions. However, this technique is not suitable for complex pulmonary resections or any other circumstance where the complexity would necessitate absolute control of ipsilateral ventilation.

When working within the diaphragmatic hiatus via a laparoscopic approach, inadvertent entry into the pleural space is not uncommon potentially creating tension physiology. If hypotension ensues, it can be resolved by decreasing the insufflation pressure to 10 mmHg.

**POSITIONING**

The lateral decubitus continues to be the mainstay for the management of the majority of pulmonary pathology (Fig. 3.1), but with increasing frequency alternative positions are used to manage lesions in the region of the posterior or anterior mediastinum. With axillary approaches and also our preference for video-assisted thoracoscopic surgery (VATS) lobectomy, the opposite shoulder is elevated with a roll to expose the anterior axillary line. This allows better direct exposure through the intercostal space and also allows one to move the edge of the latissimus to a more posterior position minimizing the need to divide even a portion of this muscle (Fig. 3.2).

With either of these positions, the hip is placed below the area of flexion in the bed so that this allows for a slight widening of the intercostal space. It is critical when performing a chest wall reconstruction with prosthesis that the table should be taken out of flexion prior to securing the mesh in place. If this step is omitted, the mesh will not be caught and may result in a flail segment.

The semi-Fowler’s position with the arms supported at right angles allows one to access both sides of the chest without a need to reposition the patient, as for a bilateral thoracoscopic sympathectomy (Fig. 3.3A and 3.3B). Apical bullectomy and pleurodesis may also be done through this approach. For additional approaches to the posterior mediastinum, as in the thoracoscopic portion of a minimally invasive esophagectomy, the prone position allows for excellent visualization of the posterior mediastinum while allowing the airway and lungs to fall away from the esophagus. For this position, the patient’s arms are placed above his head so that the scapula is brought up as high as possible, minimizing interference with access to the chest. (Fig. 3.4A–3.4C)

In contrast, access to the anterior mediastinum can be performed in the lateral decubitus as with traditional operations.
Fig. 3.1. The patient is positioned on his side with the hip below the point of flexion in the bed. The lateral and posterior chest wall is optimally exposed for this approach. A limited muscle sparing thoracotomy is delineated by the solid line and a standard posterolateral approach by the dashed line.

Fig. 3.2. The patient is again positioned in the lateral decubitus; however, the axilla is opened up and the anterior axillary line and ipsilateral breast are predominantly exposed. The axillary vertical muscle sparing incision oblique incisions are demonstrated.

Fig. 3.3. (A) The patient is positioned with both arms elevated to expose the bilateral axilla, taking care not to extend the brachial plexus. (B) The location of the port sites for a video-assisted thorascoscopic surgery sympathectomy.

or in the supine or semi-supine position. The latter positioning allows for visualization of the contralateral side of the thymus when performing VATS resections. When utilizing such positioning, access to the lateral chest wall should be planned for in advance if a combined approach will be used. In this setting, we will usually place a roll under the side of the chest we wish to expose, and pull the arm and shoulder posterior so that the cervical as well as thorascoscopic approaches can be simultaneously used without the need to reposition (Fig. 3.5).

VIDEO-ASSISTED THORACOSCOPIC SURGERY APPROACHES

Historically, video thorascoscopic procedures started with simple thoracic procedures, and the ports were placed along the line of an anticipated thoracotomy incision. Currently, port positioning is more commonly chosen based on the objectives of the operation, and the limitations of the instrumentation as well as experience of the surgeon. The potential need to convert to an open procedure no longer is a major
Fig. 3.4. (A) The patient is positioned prone with exposure of the lateral and posterior chest wall. A vacuum bean bag may be used to rotate the bed with stabilization of the patient as well as to provide increased access to the lateral chest wall. (B) Posterior esophageal duplication cyst resected with the patient in the prone position. (C) Location of port sites with patient in the prone position are demonstrated.

Fig. 3.5. The patient is positioned semi-supine with a support under the chest. This allows the ipsilateral arm to fall posterior to minimize interference with instrumentation.

Fig. 3.6. (A) Large benign solitary fibrous tumor. (B) Postoperative image of the port sites after resection of the large solitary fibrous tumor. The location of port sites was altered to facilitate dissection of the lesion at the posterior and inferior chest.

consideration as ports have become much smaller and the need to convert to a standard posterolateral thoracotomy much less likely.

Today, the complexity of cases performed with this approach has increased significantly. Re-operations after previous thoracotomy, lobectomy with mediastinal lymph node dissection, thymectomy, and resection of mediastinal lesions are all performed under thoracoscopy guidance. In these settings, port sites are strategically located in order to minimize the challenges associated with instrumentation, the bony and hilar anatomy, as well as the pathology. Given this, one must alter port location, as well as patient positioning to facilitate not only exposure but also freedom of instrumentation. Although we typically use three-port sites, we will add a fourth when needed for more complex procedures. Upper extremity positioning or other hindrances may interfere with the full mobility of instruments, and these limitations should be anticipated when planning the operative procedure. In particular, when dealing with benign disease, where margins are less of a concern, a utility port is unnecessary as tumors may be morcellated prior to extraction (Fig. 3.6A and 3.6B).

Because the nuances associated with port positioning are critical to successful performance of the procedure, we will briefly discuss the minimally invasive approaches to specific pathology.

**Video-Assisted Thoracoscopic Surgery Wedge Resection**

For any video-guided surgery, triangulation of port sites is essential to minimize instrument interference and improve visualization. Port placement is fairly standard with two usually placed along the anterior axillary line and one posterior below the tip of the scapula. We try to minimize the posterior location as the intercostal spaces are narrower and trauma to the intercostal nerve may be more likely to occur. However, if one is planning for a VATS wedge resection with subsequent lobectomy with lymph node dissection, it is important to locate the superior port along the planned incision for the utility port. In our experience,
we typically use two 5-mm ports for the superior ports and a 10-mm port for the inferior port along the anterior axillary line. The intercostal spaces are larger here to allow for placement of a stapler and this site functions as the subsequent chest tube site (Fig. 3.7A and 3.7B).

For complex procedures, port site location is modified based on anatomic and clinical factors. One must identify where the target lesion is to be found. If direct palpation is necessary to identify the lesion, we typically place the larger port site specifically within “finger reach” of the target lesion. We tend to keep two-thirds of the port sites in the 5 mm range when possible. In this setting, it is only possible to palpate through one port or pass the stapler for a wedge excision through one port and the angle and trajectory that this port takes must be taken into account. Another critical factor is the width of the patient’s intercostal spaces, as the more posterior aspect of the space is significantly narrower. We do not hesitate to enlarge an incision when necessary or resect a small segment of rib to accommodate direct palpation when one cannot identify the lesion. For any thoracoscopic procedure, the surgeon should be positioned on the side of the camera to facilitate orientation with the projected image.

**Video-Assisted Thoracoscopic Surgery Lobectomy**

For a VATS lobectomy, when placing the port sites for the diagnostic portion and then proceeding with a lobectomy, the anterior-superior port site is placed overlying the superior pulmonary vein for an upper lobectomy and above the pulmonary artery within the fissure for a lower lobectomy, as this will become the location of the utility port. There is great variation among surgeons as to the optimal location of ports for VATS lobectomy. We typically use two incisions along the anterior axillary line, one for the utility port as described above and the inferior one at the seventh intercostal space for the camera. We use a second 5-mm port posteriorly approximate one inner space below the tip of the scapula. We tend to again manipulate the patient’s ipsilateral elbow to open up the axilla, as in an axillary thoracotomy, as this allows the utility port to be muscle sparing as the edge of the latissimus dorsi muscle is reflected posteriorly and the serratus anterior muscle is split along the intercostal space. We use a soft tissue retractor as it minimizes the potential trauma from metal retractors and the exposure it provides, especially in the larger patient, is unparalleled (Fig. 3.8A and 3.8B).

Although some thoracic surgeons perform the entire procedure without moving the camera position, we typically will place the camera through the posterior port site in order to perform the posterior dissection of the airway as well as to dissect the level 7 lymph nodes.

**VIDEO-ASSISTED THORACOSCOPIC SURGERY APPROACH TO THE ANTERIOR MEDIASTINUM**

For the VATS approach to anterior mediastinal lesions, location of port placement is dependent upon the overall strategy and position of the patient. We tend to use a semi-supine position and combine a transcervical thymectomy with a left-sided VATS for thymectomy as the aorto-pulmonary window can be particularly challenging through a limited transcervical approach (Fig. 3.9). As well, for complex lesions or in the setting of mediastinal resection in patients who have undergone previous sternotomy, direct exposure is critical and we have found placement of a port in the infraclavicular fossa to be a useful position for access to the mediastinum. In this setting, the patient is either positioned supine or if in the lateral decubitus, the ipsilateral upper extremity is positioned posterior...
rather than anterior to open the access to that space. When working on lesions where margins are not an issue, there is no need for a utility port as the lesion can be morcel­lated and brought out through a 10-mm site (Fig. 3.10A and 3.10B).

Video-Assisted Thoracoscopic Surgery Approach to Posterior Mediastinum

Positioning for posterior mediastinal approaches is dependent upon the pathology and its location, as port placement for an esophagectomy, sympathectomy, or repair of a Bochdalek hernia will vary greatly. For a sympathectomy or other lesions at the apex of the chest, we use a modified semi-Fowler’s position. This allows for bilateral exposure with a single position, eliminating the additional operative time required to change the patient’s position (see Fig. 3.3A and 3.3B).

The lateral decubitus or prone position for thoracic esophageal dissection or other lesions provides excellent exposure of the esophagus. Again, benign lesions may be approached through well-placed minimally invasive ports with morcellation used for extraction (Fig. 3.11A– 3.11D).

Although for some there is a concern that one should be able to “bail out” with a posterolateral thoracotomy if necessary, we have not found this to be the case. One can convert to a lateral thoracotomy if necessary to manage bleeding or if more extensive disease than expected is found. Since in this position the lateral and posterior chest is exposed, an incision can be made, the intercostal muscles are divided, and ample open access to the chest is created. The more of these alternative approaches one uses, the more comfortable one becomes with handling these issues as they arise.

ROBOTIC APPROACHES

Although it may not have yet been reported, essentially any operation that can be performed with VATS can be performed with the robot. The challenges of nonrobotic thoracoscopic approaches lie in the lack of articulation of the instruments as well as the limitation of two-dimensional imaging. Robotic surgery mitigates these challenges given the 360 degrees of freedom offered by the instruments and the binocular camera that produces 3D visualization. However, repositioning of the camera or instruments through different port sites, when this is needed can be a challenge. This has been improved with the Da Vinci SI, as the technology allows a fourth arm so that the surgeon can alternate between instruments thus facilitating the technical performance. The ideal pathology for a robotic approach allows for the entire dissection to be performed from one strategic positioning of the camera and robotic arms, thus negating the challenges of this approach. In this setting, port placement is typically performed in a gentle arc so that the instruments focus on the area of dissection.

Fig. 3.10. (A) Computed tomography demonstrating a benign central anterior mediastinal lesion (Castlman’s). (B) Photograph demonstrating posterior positioning of the ipsilateral arm providing access to the axillary space and room for laparoscopic instruments. The superior infraclavicular port site can be seen just below the clavicle.
TRANSCERVICAL APPROACH

The transcervical approach is used in the management of a number of thoracic pathologies. Access to the neck, as well as posterior and anterior mediastinum can be achieved through a cervical incision. For thymectomy, the patient is positioned supine for the transcervical approach or with a roll under the left chest for a combined approach with VATS. An inflatable pillow is placed behind the shoulders to maximally extend the neck and allow the surgeon to work sitting at the head of the table. One must make sure that in elderly patients, they can sufficiently extend their neck to allow for adequate exposure.

A curvilinear incision is made approximately one finger breadth above the clavicular heads. The platysma is divided and subplatysmal flaps are elevated from sternal notch to the thyroid cartilage. Once this has been done, the strap muscles are separated in the midline exposing the thymus.

When exposing the esophagus for esophagectomy or a Zenker’s diverticulum, the cervical incision is made higher usually within a skin crease for improved cosmesis. Although the traditional incision for this approach has been an oblique incision along the border of the sternocleidomastoid muscle, the transverse incision allows for improved cosmesis in a highly visible area and does not limit the exposure (Fig. 3.12A and 3.12B).

POSTEROLATERAL THORACOTOMY

The posterolateral thoracotomy historically has been the most widely used approach for thoracic pathology. Although any pulmonary resection may be performed through this incision, which has led to its particular versatility, muscle sparing options and less invasive techniques have, in many centers, begun to replace this as the routine approach.

In positioning, it is important to prepare the skin over a broad area and place the drapes widely, particularly along the posterior spine. One must appropriately pad and support the upper and lower extremities so as to avoid inadvertent neurologic or pressure injury. Care must be taken with the elbows and wrists.

The landmarks for the posterolateral thoracotomy include the spine and the scapula. A gentle curve is drawn at the midpoint between the posterior border of the scapula and spine to approximately one fingerbreadth below the tip of the scapula over to the anterior axillary line (see Fig. 3.1). We tend not to use the full extent of this incision for most procedures so as to minimize tissue trauma and improve healing. Once the skin and subcutaneous tissues are divided, the latissimus dorsi is divided as well. Anteriorly, we routinely spare the serratus anterior muscle by freeing the fascial attachments to the chest wall and between the muscle and the latissimus dorsi muscle; this is done obliquely along the chest wall to avoid division of the serratus fibers. Depending on the posterior extent of the incision, additional thoracic muscles such as the trapezius or rhomboids may need to be divided. This is particularly important when elevating the scapula off of the chest wall as in a chest wall resection or posterior approach to an apical lung tumor.

The scapula is elevated with a right-angled retractor, and the ribs are counted by manual palpation. Relying on the first rib can be misleading because the posterior first rib may be obscured. One can avoid errors by using the insertion of the

Fig. 3.11. (A) Computed tomography demonstrating a posterior mediastinal schwannoma. (B) Intraoperative view through a 5-mm camera of the resected schwannoma video-assisted thoracoscopic surgery resection of a large schwannoma. (C) The lesion is placed in a sac and the edges of the sac are retrieved through the 10-mm port site. The mass is morcellated prior to extraction. (D) The 10-mm port site is used to place the chest tube.
posterior scalene muscle onto the second rib as a reference to begin the rib count.

A fifth intercostal space thoracotomy incision is made by dividing the intercostal muscles directly above the superior margin of the sixth rib. This avoids injury to the neurovascular bundle that lies just inferior to the fifth rib in a slightly recessed groove. The division along the intercostal muscles extends fairly far beyond the limits of the skin incision to maximize rib separation. In patients with brittle ribs, excising a subperiosteal segment of the sixth rib at the costovertebral angle, the so-called shingling, can help to avoid rib fracture. A 1-cm segment is removed to minimize discomfort from periosteal friction following reapproximation. Resection of larger segments of rib is reserved for repeat thoracotomies. In this situation, entering the pleural space through the bed of the resected rib improves exposure for adhesiolysis of the pleural space. In approaching diaphragmatic pathology, the seventh or eighth intercostal space is suitable for optimal exposure.

Once the chest is entered, a Finochietto-type retractor is used to separate the ribs. For smaller incisions, smaller retractors provide adequate exposure. On completion of the procedure, a single modified thoracotomy tube usually provides adequate drainage. Additional drainage holes are cut in the tube, and it is tunneled transversely so as to lie in the diaphragmatic sulcus and course posterior to the apex of the chest; thus, it functions as both a basilar and an apical tube. Large absorbable sutures are used to reapproximate the ribs. One must be careful not to over approximate the ribs because this may contribute to postoperative pain. The remainder of the incision is closed meticulously in layers with absorbable sutures.

This incision is suitable for pulmonary resections and extrapleural pneumonectomies. For esophageal disease, depending on the location of the pathology, the incision may be made an innerspace or two lower in order to get access to the hiatus. In this setting, it is useful to place a traction suture on the diaphragm in order to retract it out of the way. In addition, when on the left side, one may place a suture in the pericardium to pull the heart up and out of the way improving exposure in a challenging area. When performing an extrapleural pneumonectomy, often an additional thoracotomy, two intercostal spaces below can be divided to improve access for the diaphragmatic resection as well as the reconstruction.

**AXILLARY THORACOTOMY (MUSCLE SPARING)**

The axillary thoracotomy has replaced the posterolateral thoracotomy as my incision of choice for open resections. Because of the inherent limitations of exposure, it did not initially gain widespread use. Improved stapling devices and increased surgical experience have demonstrated its superiority. The advantages of this incision are several: (1) the major thoracic muscles are left intact, (2) there is increased ease and speed of both opening and closing the chest, and (3) cosmesis is improved. Because the incision is small it may be difficult for two surgeons to have adequate simultaneous visibility. In addition, most posterior chest wall resections are more optimally suited for a posterolateral thoracotomy because elevating the muscles and scapula off of the chest wall facilitates the dissection. We have found that having a thoracoscope within a future chest tube site allows the scrub nurse, student, and others to follow the operations. In addition, the camera facilitates division of the inferior pulmonary ligament which on occasion may be a challenge with the incision being kept particularly small.

Some authors have suggested that complex resections, such as bronchial sleeve resections or pulmonary arterial reconstructions, should not be performed through this approach, but we have not found this to be the case. We routinely perform complex procedures through this incision.

The patient is positioned in the lateral decubitus position with a few adjustments. The elbow is rotated cephalad to open up the axilla (see Fig. 3.2). The body is rotated posterior so that more of the anterior and lateral chest is exposed. The skin incision for this approach may be oriented vertically or obliquely. A 5- to 7-cm incision is made along the anterior axillary line aligned with the anterior–superior iliac spine centered usually on the nipple in male patients or the fourth intercostal space. One should avoid placing this incision too far posterior because injury to the long thoracic nerve may occur. The intercostal brachial nerve runs in the superior half of the incision and should be preserved if possible. Patients should be counseled preoperatively that...
they may have numbness in the area of
distribution of this nerve. In addition,
numbness along the lateral breast is
common with this incision, though this
eventually resolves.

After the subcutaneous tissues are
divided, the pectoralis major muscle is
undermined and the anterior border of
the serratus anterior muscle is visualized.
Often the pectoralis minor muscle must
be reflected in order to expose the ante­
rior insertions of the serratus muscle. The
serratus insertions are mobilized off the ribs
by reflecting the attachments or split along
the fifth interspace. Thus, the insertions of
the serratus anterior muscle are mobilized
and reflected off of the fourth and fifth ribs.

Because this is essentially an anterior inci­
sion for pulmonary resections, we enter the
chest through the fourth intercostal space,
whereas for thoracic tracheal resec­
tions we enter through the third. Because this
incision is anterior, one cannot rely on the
posterior scalene muscle for counting the
ribs. The first rib is identified by palpating
the tubercle. If one is unsure of the first rib,
one can reach over the superior border and
identify the thoracic outlet because there are
no intercostal muscles above the first rib.

The intercostal muscles along the appro­
priate space are divided as in a postero­lat­
eral thoracotomy. The intercostal incision
is carried well beyond the limits of the skin
incision, almost to the level of the vertebral
bodies. The incision in the intercostal space
is kept away from the overlying chest wall
muscles and is facilitated by progressive
opening of the rib spreader, which provides
countertraction. A pediatric Finochietto­
type rib spreader is used to separate the ribs,
and a Balfour retractor is placed perpendic­
ular to the rib spreader to retract the skin
and subcutaneous tissues. The skin is quite
pliable, and thus excellent exposure can
be achieved through this relatively small
skin incision because the intercostal inci­
sion essentially rivals or even exceeds that
made with a posterolateral incision. At the
completion of the procedure, a single chest
tube is placed, pericostal sutures are placed
to reapproximate the ribs, the insertions of
the serratus anterior muscle are sewn to the
pectoralis minor muscle anteriorly, and the
rest of the closure proceeds as usual.

**ANTERIOR THORACOTOMY**

With recent trends toward minimally inva­
sive cardiac surgery, the anterior thoraco­
tomy has regained an element of popularity.
Otherwise, it remains the incision of choice
for open-lung biopsy and emergent thora­
cotony. Open-lung biopsy, in contrast to a
video procedure, may be the approach of
choice in hypoxic, ventilated patients who
require lung biopsy. These patients may not
tolerate single-lung ventilation, and this
procedure can be performed while both
lungs are being ventilated by a single-lumen
endotracheal tube.

The patient is positioned with a roll
under the operative side. The ipsilateral arm
is placed over the patient on an arm rest or
alongside on a support. An incision is made
from the anterior axillary line curving
under the breast toward the sternum. The
fourth or fifth intercostal space is entered.
For an open-lung biopsy, we make a fairly
limited incision, approximately 3 cm in
size. For an emergency thoracotomy, the
incision is obviously much larger and can
be extended across the sternum to increase
exposure as needed (Fig. 3.13).

**MEDIAN STERNOTOMY**

The median sternotomy is most commonly
used for cardiac surgical procedures but
can be a useful tool in general thoracic sur­
gery operations requiring access to both
pleural spaces or for resection of mediastin­
al disease.

The patient is placed supine with one
or both arms tucked at the side. A roll is
placed behind the shoulders to extend the
neck and expose the sternal notch. The
midline of the sternum is marked, and a
knife divides the skin (Fig. 3.14). The subcu­
taneous layers are divided though the
decussating fibers of the pectoralis major
muscle, and the midline of the sternum is
carefully marked with cautery. Palpating the
intercostal spaces along the sternum allows
one to accurately identify the midline. The
interclavicular ligament is divided, and
the retrosternal space is bluntly dissected.
The xiphoid tip is dissected, and again the
space posterior to this is developed. A
reciprocating saw is used to divide the
sternum. The bleeding periosteal edges
are carefully and judiciously cauterized.
An appropriate sternal retractor is used
to gradually spread the two sternal edges.
Brachial plexus injuries may occur when the retractor is opened too quickly or too widely.

At the conclusion of the procedure, one or two chest tubes are placed. Wires are used to reapproximate the sternum. We place two in the manubrium and four around the sternal edges. The pectoralis fascia is closed over the sternum, and the remainder of the wound is closed in layers. One should thoroughly irrigate the wound and carefully obliterate any potential spaces at the time of closure to attenuate the possibility of infection. Newer sternal closure systems that employ plates and screws may also be used for sternal closure and may be especially useful for the more fragile sternums.

**BILATERAL THORACOSTERNOTOMY (CLAMSHELL)**

The bilateral thoracosternotomy had previously been the incision of choice for bilateral lung transplantation. Due to complications relating to the transverse sternal division, most centers have abandoned this technique in transplant patients. However, it remains a very useful approach when wide access to both pleural spaces is required, as in selected patients with bilateral pulmonary metastases or those with large tumors of the anterior mediastinum, although admittedly it is used sparingly.

A transverse skin incision is made extending from one anterior axillary line along the inframammary crease to the other anterior axillary line (Fig. 3.15). The subcutaneous tissues are divided, and the fourth or fifth intercostal space is identified. The intercostal muscles along this space are divided, and the internal mammary vessels are identified and ligated prior to dividing the sternum. The Lebsche knife is used to divide the sternum transversely. Rib spreaders are usually placed on both sides to allow for maximal exposure. After the procedure, paracostal sutures are placed and the sternum is reapproximated with wire.

**THORACOSTERNOTOMY (HEMICLAMSHELL)**

The thoracosternotomy is a useful approach for large central pulmonary lesions and other special situations. Such tumors can interfere with one’s access to the hilum, making the dissection and proximal control...
of the pulmonary artery difficult (Fig. 3.16). With the thoracosternotomy, one can approach the dissection anteriorly and dissect the hilar vessels from within the pericardium without being impeded by a large tumor as occurs when trying to approach the hilum from a posterior approach. In addition, the brachiocephalic vessels are much more readily seen, exposed, and controlled through this anterior approach. This incision is extremely versatile, and we do not hesitate to use it for these special situations.

The patient is positioned supine or with a small support elevating the ipsilateral chest. Both arms may be tucked, or the ipsilateral arm may be extended if additional exposure of the lateral chest is needed. The initial skin incision is limited to the inframammary portion and the fourth intercostal space is entered to assess resectability and ensure that there is no diffuse pleural spread or other reason why the entire incision should not be made. The skin incision is then extended over to the sternum and up toward the sternal notch and then for a short distance along the anterior border of the ipsilateral sternocleidomastoid muscle. The subcutaneous tissues are divided through the decussating fibers of the pectoral muscles and then along the fourth intercostal space. Before dividing the sternum, the intercostal muscles in the fourth space are divided up to the mammary vessels. These are dissected, doubly ligated, and divided in advance. The sternal saw is used to perform a partial sternotomy curved out to the fourth interspace. A hemisternal retractor of the type used for harvesting the internal mammary artery is then placed and used to elevate the chest wall. Although the skin incision will usually be limited to the anterior or posterior axillary line, the division of the intercostal muscles should extend back further posteriorly to allow for full elevation of the chest wall. This will assist in avoiding inadvertent fractures.

**ANTERIOR CERVICO THORACIC APPROACH (MODIFIED DARTEVELLE APPROACH)**

For pathology at the level of the thoracic outlet or apex of the chest, a modified thoracosternotomy is used. This particular incision is used most commonly for apical intrathoracic pathology that may or may not involve resection of the apical chest wall.

A double-lumen tube is used. The patient is placed supine, with a soft support under the shoulders. The head is turned away from the side of pathology. An L-shaped skin incision is made along the anterior border of the ipsilateral sternocleidomastoid muscle to the sternal notch and then curving out below the clavicle going toward the deltopectoral groove (Fig. 3.17). The retrosternal space is freed with blunt dissection. The intercostal muscles are divided into either the first or second intercostal space, whichever is more suitable for the pathology. We enter the intercostal space laterally and divide the muscular fibers medially until meeting the manubrium. During this, we use blunt dissection to sweep the mammary vessels away from the chest wall. The Lebsche knife is used to divide the manubrium in an L-shaped fashion from the midline down to the appropriate intercostal space (Fig. 3.17). If the chest wall is to be resected, the cut with the Lebsche knife is extended to divide the first rib just lateral to the sternum. The internal mammary vessels are divided after the manubrium and clavicle have been separated. This improves exposure of the vessels as they come through the outlet, avoiding inadvertent
injury to the phrenic nerve. A hemisternal retractor is used to elevate the chest wall and provide exposure.

Given the angle the ribs take from anterior to posterior, exposure of the posterior third intercostal space posteriorly can be viewed through the first intercostal space anteriorly. The extent of disease is evaluated, and the chest wall may be divided in the appropriate locations as identified by palpating the lesion. After all of the chest wall and intercostal attachments have been completely divided, the chest wall bloc with the attached underlying pulmonary parenchyma is dropped into the thorax through the defect. The pulmonary parenchymal resection may be completed without difficulty through this defect.

On completion of the procedure, a chest tube is placed, and the chest wall is reconstructed when necessary. Anterior defects should routinely be reconstructed with a rigid prosthesis to prevent a "flail-like" physiology especially in the patient with borderline pulmonary function. To close this incision, the divided interspace is reapproximated with paracostal sutures and the manubrium is reapproximated with No. 5 stainless steel wires. The remainder of the wound is closed by reapproximating the muscle and fascia in the usual fashion.

**THORACOABDOMINAL INCISION**

The thoracoabdominal incision provides wide exposure of the lower chest, retroperitoneum, and upper abdomen, especially the diaphragmatic hiatus. It is a common approach for the management of abdominal aortic aneurysms when done as an open procedure, occasional distal esophageal tumors, and anterior approach to the lower thoracic and lumbar spine, and in those patients who may have undergone previous distal esophageal or upper gastric procedures. As well, a right-sided thoracoabdominal incision may be used for an Ivor Lewis type of approach to esophagectomy. In this setting, for performing the traditional open approach, we use a vertical muscle sparing incision for the thoracic portion. Positioning in this fashion obviates the need for repositioning during the procedure.

The exact location of the skin incision varies in relation to the pathology. The chest portion of the incision may be over the sixth, seventh, or eighth intercostal space, and the abdominal portion may be either midline or paramedian in location (Fig. 3.18, previous edition Fig. 3.10). The patient is positioned supine, usually with a small support extending from the hip to chest of the ipsilateral side. The arm can be supported at the patient’s side, extended out at 90 degrees or suspended across the chest. The skin incision is made extending from the anterior axillary line, across the costal arch onto the abdomen. The costal arch and the intercostal muscles are divided. The diaphragm can be divided radially from the chest wall to the hiatus or circumferentially leaving 3 to 4 cm along the chest wall for later reapproximation. One must be careful to avoid injury to the phrenic nerve. A rib spreader is placed to separate the ribs, or a self-retaining type of retractor that attaches to the operating table may be used to provide exposure in both the chest and abdomen.

On completion of the procedure, a chest tube is placed. The diaphragm is closed with large nonabsorbable, interrupted sutures. We routinely excise the edges of the costal arch to prevent postoperative pain and discomfort that can result from overlapping of the costal edges. Pericostal sutures are used to reapproximate the ribs, and the abdomen is closed in layers, again with large nonabsorbable sutures for the fascia.

**SUMMARY**

Given the increased focus on minimally invasive surgery, alternative strategies have been developed to deal with almost every type of thoracic pathology. Time will tell which ones ultimately prove to be most useful to the surgeon and most beneficial to the patient. Unlike open approaches, which are somewhat forgiving given the wide access provided, for less invasive options additional factors must be considered. The ergonomics of the instruments, angle of approach, and the surgeons’ ability to handle the pathology...
all contribute to the preoperative planning strategy. Careful consideration of all the potential challenges associated with positioning, the anatomy and pathology, as well as instrumentation are critical to the successful performance of the procedure.

SUGGESTED READINGS

Dr. Marshall has provided a detailed and complete summary of the incisions available to the thoracic surgeon. As the current generation of thoracic surgical residents is likely being exposed mostly to minimally invasive approaches, it still remains important to have the full range of incisions in one’s armamentarium since situations clearly will arise where a minimally invasive approach is not either optimal or feasible. Patient positioning is important for each particular incision both to maximize exposure and to protect against injury either from pressure or stretch. Working together with the anesthesiologist will maximize the chance of avoiding injury.

When working via a minimally invasive approach, the surgeon should be intimately familiar with the procedure to be followed should the need arise to rapidly open the chest. I particularly worry about a pulmonary artery injury when utilizing either a VATS or robotic approach. The initial maneuver, of course, should be to control hemorrhage simply with pressure applied over the bleeding point while help is mobilized and blood for transfusion is made available. Having appropriate help in an emergency situation cannot be overemphasized especially if there is difficulty controlling the bleeding. It should never be considered a sign of weakness to call for the help of a colleague in such a situation.

I have found the thoracosternotomy (hemiclamsheil) incision particularly useful when dealing with large pulmonary lesions since it provides ideal exposure of the pulmonary hilum that otherwise would be obscured if approached via a posterolateral approach. From this approach, it is usually best to divide the appropriate pulmonary vein as the first step in a resection.

The anterior cervicothoracic incision also has proven to be extremely versatile for lesions occurring at the thoracic inlet. The approach provides excellent exposure of the lower cervical and upper thoracic spine, especially at the T1 level, a region that is difficult to expose either from the neck or from the chest. Leaving the sternoclavicular junction intact by dividing and elevating the manubrium avoids problems with postoperative upper extremity dysfunction. This approach essentially has replaced the posterior approach when dealing with an apical lung tumor or so-called Pancoast’s tumor. Even when the lesion appears to be posterior, this anterior exposure is the procedure of choice since the anterior—posterior distance at the apex is extremely short, so there is no issue in dealing with the posterior chest wall at this level. When chest wall is to be resected, it is important to divide the first rib at the sternum as one competes the division of the manubrium. Otherwise, if the first rib is left intact, it is elevated with the manubrium making its excision particularly difficult. The exposure of the brachial plexus and brachiocephalic vessels is optimal from this approach and is much more readily available than when approached through the extended posterior thoracotomy. The incision is also considerably less morbid than the extended Paulson-type posterior incision that mandates division of the lattissimus dorsi, serratus anterior, rhomboids, and trapezius muscles in order to elevate the scapula off the chest wall to gain exposure to the first rib. Utilizing the anterior cervicothoracic approach does require the surgeon to be intimately familiar with the anatomy of the thoracic inlet.

GENERAL INTRODUCTION TO PULMONARY RESECTIONS

Pulmonary resection is the operation that defines the thoracic surgeon. The specialty of thoracic surgery is relatively new dating back to less than 50 years but really being defined during the past 30 years. Because of problems relating to positive pressure ventilation in the patient with an open chest, the development of anatomic pulmonary resection moved slowly. The initial procedure performed for a carcinoma of the lung was a pneumonectomy carried out by mass ligation of the pulmonary hilum with subsequent suturing of individual hilar structures. During the first four decades of the 20th century carcinoma of the lung was an uncommon disease and most pulmonary resections were performed for inflammatory conditions or tuberculosis. Most lung cancers were treated by total removal of the lung when they were deemed operable and this clearly was the operation thought to be required. Lesser resections were reserved for benign disease, mostly infectious problems. It took a number of years before surgeons recognized that an anatomic resection of a lobe, though a more difficult operation, provided an acceptable alternative for the treatment of lung cancer, not unlike the recognition that a more conservative resection than a radical mastectomy could be done for breast cancer with comparable survival rates.

Recognizing that surgical excision is the optimal treatment for otherwise operable lung cancer, it is important that the appropriate procedure be performed. Lobectomy remains the definitive resection since it is an anatomic resection that assures removal of the regional lymph nodes that course along the lobar bronchus and thus provides the best staging information and local control. Doing less than a lobectomy must be considered a compromise though often it is tempting to consider a nonanatomic wedge excision for small primary tumors. Not only does a wedge excision not include the lobar bronchus, precluding evaluation of lobar lymph nodes, but usually also provides only a minimal parenchymal margin and thus is accompanied by a significant incidence of local recurrence. The Lung Cancer Study Group (LCSG) addressed the question of lobectomy versus limited resection for T1N0 lesions (tumor <3 cm, negative lymph nodes) in a prospective randomized trial. The initial analysis of the data demonstrated an increased incidence of local recurrence in the limited resection group (>30% incidence) but failed to demonstrate a decrease in survival. The final analysis, however, revealed superior survival for patients in the lobectomy group. A number of other studies have looked retrospectively at patients undergoing limited resection, including anatomic segmental resection, and have demonstrated long-term survivors but the LCSG study stands as the only large randomized trial. Limited resection is associated with lower morbidity and decreased hospital stays but the best evidence supports a higher incidence of loco-regional recurrence when compared to lobectomy. That said, limited resection may be comparable to lobectomy in the elderly (>70 year old) and in those with small peripheral tumors.

There are patients in whom lobectomy is not feasible and a lesser resection offers the best alternative, though admittedly a compromise. Patients in this category are those with borderline pulmonary function or those who have had previous pulmonary resections. Whenever possible the lesser resection should be an anatomic segmental resection, which by definition involves taking the appropriate segmental artery and vein as well as the segmental bronchus with its accompanying lymph nodes. Wedge resection, a nonanatomic form of resection where the bronchovascular structures are not isolated and taken separately along with regional lymph nodes, is another alternative though not ideal for patients with primary lung cancers. With the advent of videothoracoscopic techniques and the simplicity of wedge resection via this approach for a time there was renewed interest in utilizing this technique for T1N0 lung cancers. The American College of Surgeons Oncology Group (ACOSOG) has an ongoing study looking at limited resection combined with local implantation of radioactive seeds to assess whether there is a decreased incidence of local recurrence and whether this translates into a survival benefit. Preliminary results at 60 and 90 days show no increase in morbidity with the addition of brachytherapy when compared with sublobar resection alone. As it currently stands based on the LCSG data, wedge excision mostly should be avoided and patients who are found to have a primary lung cancer should be offered the best possible procedure which is, to the best of present knowledge, a lobectomy. Wedge resection, at best, is a compromise and patients who otherwise can tolerate an anatomic resection are not well served by having a lesser procedure, at least based on the best evidence to date.

This has become even more important as we are identifying more early stage, small lung cancers picked up in patients who present themselves for screening spiral computed tomography (CT) scans. As noted above sublobar resection of small peripheral tumors, especially some of those identified on screening spiral CT scans, may have a survival comparable to lobectomy.

Prior to operation a decision must be made regarding which, if any, other studies should be carried out. The type and extent of the staging evaluation depends on a number of clinical factors. At a minimum patients should have a recent chest radiograph and CT scan of the chest. Most, if not all, should have a recent set of pulmonary function studies including diffusion capacity. Positron emission tomography (PET) scanning has become standard for the evaluation of a solitary pulmonary nodule and there is convincing evidence of its usefulness in staging the medias­tinum as well. The fluorinated glucose used for the PET scan is trapped preferentially in malignant cells as opposed to normal cells and thus shows up as hot. Numerous studies have looked at the sensitivity and
An important aspect of the preoperative evaluation of a patient with lung cancer is the assessment of pulmonary function. Not all patients undergoing thoracotomy require pulmonary function testing but the majority of patients with lung cancer also have some element of underlying lung disease as a result of the same risk factor that is associated with their cancer, for example, cigarette smoking. Assessment of pulmonary function serves both to identify those patients at a significantly increased likelihood of postoperative morbidity as well as those patients who stand to benefit from preoperative manipulations designed to attenuate those risks. There is no single best test to evaluate pulmonary function in a patient who is slated to undergo pulmonary resection. Also there are no absolute values that contraindicate resection though using a combination of studies it is at least possible to make a judgment as to which patients are at an increased risk for postoperative morbidity or mortality. Preoperative spirometry to measure flows and volumes should be performed. Important measurements include forced expiratory volume in 1 second (FEV1), maximal voluntary ventilation (MVV), diffusing capacity, FEV1/forced vital capacity (FVC) ratio, and the ratio of the residual volume (RV) to total lung capacity (TLC). An FEV1 of less than 40% of predicted has a high (approaching 90%) likelihood of pneumonectomy. The surgeon operating on patients with compromised lung function have to be strongly motivated toward resection. These patients are not the ones to be talked into an operation even if their other treatment options are limited; they really have to be motivated. The major morbidity and potential mortality in these patients occur in the early postoperative period but one must also keep in mind the long-term sequelae of the resection of lung parenchyma in these individuals. Paradoxically there may be some improvement in lung function following pulmonary resection in these patients especially if the lung parenchyma removed receives only a minimal amount of the pulmonary perfusion. Most commonly this occurs with a heterogeneous pattern of emphysema with the upper lobe being the most diseased portion of parenchyma. A preoperative quantitative ventilation–perfusion lung scan is useful in assessing the significance of the loss of lung parenchyma. An estimate of the predicted postoperative FEV1 may be obtained by subtracting the percentage removed by the proposed resection based on the percent of perfusion received by that area of lung parenchyma. A residual FEV1 of less than 800 ml has been associated with an increased risk of postoperative morbidity and mortality but this is entirely dependent on what percent of the predicted FEV1, the 800 ml represents. For instance, in a 50 kg female 800 ml may represent a predicted postresection FEV1 of 60% or more. An algorithm for the preoperative assessment of risk in patients with lung cancer is presented in Figure 4.1.
Some patients may undergo invasive staging prior to pulmonary resection. The decision to perform mediastinoscopy may be based on CT scan findings of enlarged mediastinal lymph nodes and the results of the PET scan. The criteria for defining “enlarged” vary and the sensitivity and specificity of the technique vary depending on the size that is set. We perform mediastinoscopy when lymph nodes greater than 1.5 cm in size are seen on the CT scan. Others perform mediastinoscopy on all patients prior to pulmonary resection recognizing that the majority of procedures will reveal only nodes without evidence of metastatic disease. Mediastinal nodes that are positive on PET scan mandate the need for mediastinoscopy unless there is such bulky adenopathy seen on CT scan that tissue confirmation would be redundant. EBUS assessment of the mediastinum with selective needle aspiration biopsy also is being used more frequently to interrogate the mediastinum.

Whether mediastinoscopy is used selectively or routinely, the key point is accurate staging of the mediastinum in the patient with lung cancer. If mediastinoscopy is performed, it is important that lymph node material be obtained for pathologic examination. Accurate mediastinal staging mandates at the least mediastinal lymph node sampling at thoracotomy or, preferably, complete systematic lymph node dissection. The problem with lymph node staging alone is the issue of how lymph nodes are chosen to be sampled, a problem not present when a complete lymph node dissection is carried out. Mere palpation of a node or an assessment of nodal size will miss nodes harboring intranodal or microscopic disease. It is not clear what percentage of nodal disease is missed with a staging procedure because of the variability in the selection of nodes to be sampled and the lack of a study where nodes are first sampled followed by a complete lymph node dissection. From our own experience 10% to 20% of resections where mediastinal lymph node disease is not suspected result in positive lymph nodes being identified by the pathologist. An operation without lymph node staging information must be considered incomplete. Accurate staging allows the surgeon to discuss prognosis realistically with the patient and allows the patient the opportunity to either participate in a trial of postoperative adjuvant therapy or be evaluated for treatment outside of a protocol setting. With prospective randomized clinical trials demonstrating improved survival of patients with completely resected N1 or N2 disease treated with postoperative adjuvant chemotherapy, the quality and completeness of the intraoperative staging has become even more important.

Despite the bias on the part of most physicians that postoperative radiation therapy is of value in resected patients who are found to have either N1 or N2 disease there are no prospective data that demonstrate a survival advantage in patients so treated. One prospective randomized trial of postoperative radiation therapy versus no further treatment for resected patients with squamous cell carcinoma demonstrated a significant reduction in local recurrence but absolutely no difference in survival. A randomized trial conducted by the collaborative efforts of the national cooperative cancer groups compared postoperative chemotherapy (cisplatin, VP-16) and radiation therapy with radiation therapy alone. This trial required that patients either have mediastinoscopy performed or have a completely negative CT scan in addition...
to mandating what lymph nodes had to be sampled at the time of thoracotomy. The results of this trial showed no advantage for the combined radiation therapy and chemotherapy arm over radiation therapy alone and no significant difference when compared to historic controls. Interestingly, there did appear to be a survival advantage in the subgroup of patients who had mediastinal lymph node dissection as opposed to lymph node sampling only.

Long-term survival following pulmonary resection depends both on characteristics of the primary tumor (T stage) and presence or absence of lymph node disease (N stage). Any analysis of survival is greatly dependent on how thoroughly the lymph nodes are staged, as discussed above. These data, accumulated from studies performed by the LCSG, are particularly enlightening because of the stringent requirement for nodal staging that was mandated for entering patients into these studies. Thus, when a patient was staged as N1 we can be assured that was an accurate staging evaluation since the mediastinal lymph nodes would have been sampled and found to be free of tumor.

**INTRODUCTION TO RIGHT-SIDED RESECTIONS**

There are a number of significant anatomic features specific to right-sided pulmonary resections. The right main pulmonary artery is relatively long and courses posterior to the superior vena cava and traverses the carina. This extra length of the artery, at times, is an advantage for some proximal lesions that in a similar location on the left side would not be resectable because of the short length of the left main pulmonary artery relative to the bifurcation. The distance between the carina and the origin of the right upper lobe bronchus usually is less than 2 cm and the carina is readily mobilized from the right side. Access to the proximal left main stem bronchus is significantly easier from the right side compared to the left side where the aortic arch limits access both to the origin of the left main bronchus and the carina. Mobilization of the carina is not possible from the left chest and even visualization of the carina from the left is difficult. Carinal resections are preferentially performed through a right thoracotomy or, at times, through a median sternotomy.

The superior mediastinum, the space accessed by the mediastinoscope, is well visualized from the right side. The area bounded by the azygous vein (inferior), the trachea (posterior), the subclavian vein (superior), and the superior vena cava (anterior) delineates this compartment whose lymph node-bearing contents may be removed en bloc from the right side. No such access exists on the left side where the left paratracheal nodes are relatively inaccessible because of the location of the aortic arch. As mentioned above, with the access afforded to the carina from the right side it follows that the subcarinal space is readily dissected for lymph node removal. The subcarinal space also is easily accessed on the left side as well.

On the right side the azygous vein is an important anatomic landmark. The vein courses from posterior to anterior across the main stem bronchi to drain into the superior vena cava. Just inferior to where it crosses the main bronchi is the origin of the upper lobe bronchus, a key anatomic feature. Rarely is it necessary to divide the azygous vein but it may be taken with impunity if involved by tumor or limits access to the lymph node-bearing area.

In assessing resections from the right side the upper lobectomy probably is the most straightforward resection though the location of the posterior segmental arterial branch may, at times, be problematic. Right lower lobectomy is complicated by the location of the middle lobe artery and bronchus and the middle lobectomy is considered difficult by some because of the minor fissure.

**SURGICAL TECHNIQUE**

**Right Upper Lobectomy**

Right upper lobectomy is the prototypical pulmonary resection and is a good starting point for the trainee just starting out in pulmonary surgery. The long right main pulmonary artery with the apical-anterior branch and the discrete takeoff of the upper lobe bronchus makes this an ideal resection. The so-called truncus anterior, the apical-anterior branch of the pulmonary artery, also facilitates segmental resections of the right upper lobe. Once this branch is divided the segmental bronchi are easily visualized.

A left endobronchial double-lumen tube is placed to allow for single-lung ventilation so that the right lung is collapsed for the lobar resection.

With the patient positioned on the left side (left lateral decubitus position), the chest is entered through either a standard posterolateral thoracotomy incision or a vertical auxiliary muscle-sparing incision. The chest is entered through the fifth intercostal space for the posterolateral incision or the fourth intercostal space for the more anterior muscle-sparing incision. The hilum and mediastinum are palpated to assess the extent of involvement and determine resectability. Access incisions for VATS lobectomy are described in detail in the chapter dealing with VATS pulmonary resection but a small utility incision usually is made anteriorly not only to facilitate the dissection but also to allow for removal of the lobe from the chest. Whether done by a VATS approach or open thoracotomy, the dissection of the pulmonary hilum essentially is the same in that the superior pulmonary vein, the pulmonary arterial branches, and the lobar bronchus must all be taken individually.

The lung is retracted posteriorly and the hilar pleura anteriorly and superiority is incised. The superior pulmonary vein is identified and dissected distally toward the lung parenchyma and proximally to the pericardial reflection. The vein is encircled once the appropriate plane of dissection is entered. Care must be taken to avoid injury to the pulmonary artery which lies directly posterior to the superior pulmonary vein (Fig. 4.1). The middle lobe venous branch, which usually drains to the superior pulmonary vein, is identified and preserved. This vein almost always is a tributary of the superior pulmonary vein but occasionally may be found entering the inferior pulmonary vein. Infrequently aberrant venous drainage on the right side, usually a small venous branch emptying directly into the vena cava, may be encountered. Lying just superior and posterior to the vein is the right main pulmonary artery. The artery is dissected circumferentially and followed proximally where it is observed as it courses posterior to the superior vena cava. The artery is easily encircled with a finger once the appropriate plane of dissection is entered. For an open thoracotomy, proximal control of the artery is usually established in this fashion if there is even a suggestion that the dissection may be difficult. It is not necessary to encircle the right main pulmonary artery in every case but one cannot be too safe in taking the extra precaution of having proximal control. After encircling the artery an umbilical tape is passed and a Rumel tourniquet is placed. Should the artery be inadvertently entered it is a simple matter to snug down on the tourniquet and control the bleeding. The artery is dissected distally and the apical-anterior arterial branch is identified (Fig. 4.2). This usually occurs as a common trunk but the individual segmental branches may arise separately from the main artery with the
branch to the anterior segment coming off the artery as the most proximal branch.

Dissecting out the pulmonary artery and its branches differs significantly from the manner in which other arteries are handled. Lacking a muscular coat the main strength of the artery comes from the intima. Thus the artery is extremely fragile and must be handled with the utmost care. When dissecting the artery great care must be taken in using any "spreading" maneuver. Whereas in peripheral vascular surgery it is perfectly acceptable to dissect out an arterial branch by using the scissors to spread adjacent tissue, this move, if applied to a pulmonary arterial branch, can easily result in avulsion of the branch from the artery trunk. Likewise, when attempting to use a right angle to encircle a branch of the pulmonary artery little or no force should be applied since one gets no tactile cues from this artery. An arterial branch should be completely dissected free circumferentially prior to trying to pass a right-angled clamp. To do this the thin connective tissue overlying the artery is grasped with a forceps and lifted to allow a cut by the scissors. Once the correct plane on the artery is reached, a closed, blunt-tipped scissors is used to gently push the artery away while continuing to hold the incised tissue. This rapidly creates the plane of dissection and frees up the adjacent arterial branch. If an attempt to pass a right angle is met with any resistance, further dissection should be performed rather than persisting with the right angle and potentially perforating the back wall of the arterial branch. A peanut dissector may also be used to dissect the pulmonary artery once the correct plane of dissection on the artery is encountered but I personally do not favor use of this instrument.

Once the artery has been identified, the dissection proceeds superiorly along the hilum to enter the plane of the bronchus. The azygous vein is a significant landmark. This vein crosses the right main stem bronchus just superior to the origin of the right upper lobe bronchus. The vein courses from posterior to anterior and the bronchus lies medial to the vein. Once the artery is dissected away from the bronchus, it is possible to encircle the upper lobe bronchus at this point if deemed necessary. At times it is advantageous to divide the bronchus first, especially if the primary tumor or lymph nodes involve the branches of the pulmonary artery.

The lung is retracted anteriorly by the assistant to reveal the posterior aspect of the hilum. Unlike operating in the abdomen, it quickly becomes clear when doing pulmonary surgery that the surgeon must be familiar with the anatomy and especially the relationships between structures from both an anterior and posterior orientation. In the chest the surgeon needs to think in three dimensions. To facilitate the performance of an upper lobectomy dissection is begun by incising the overlying pleura in the bifurcation formed by the upper lobe bronchus and the bronchus intermedius (Fig. 4.3). This is one of the most significant moves of the entire procedure and if understood it greatly simplifies and speeds up the operation. Taking care to coagulate small bronchial vessels that are present in this "crotch" the pleura is incised. A lymph node is a constant finding in this location and the dissection frees this node anteriorly away from the bifurcation. The upper lobe bronchus may be encircled at this point and taken, if desired (inset, Fig. 4.3). Just anterior to this lymph node, however, lies the branch of the pulmonary artery to the superior segment of the lower lobe, which is easily visualized from this posterior approach. Once this arterial branch is identified, the posterior portion of the major fissure may be completed with a firing of the linear stapler (Fig. 4.4). The lower lobe superior segment arterial branch is the most posterior branch of the artery within the fissure and the stapler may be safely passed just posterior to the branch. The pleura within the fissure needs to be incised and the appropriate location for placement of the stapler may be found by placing the forefinger in the crotch just dissected posteriorly and the thumb in the fissure. The fissure at the appropriate spot is quite thin and may be further thinned out by finger dissection of the parenchyma held between the thumb and forefinger. This move is safe because the location of the artery is known and it has been dissected free. It avoids extensive dissection in the fissure in a search for the pulmonary artery. Until the location of the artery is known, firing a stapler across the fissure, as is commonly done, adds little; it really brings you no closer to the artery. Taking advantage of the anatomy posteriorly allows easy identification of the artery in the fissure without actually dissecting the fissure and thus avoids air leaks. It is important to remember that the fissure, for that matter any fissure, is defined by the artery. Once the artery is identified and dissected in the correct plane, the posterior portion of the major fissure is very simple to complete.

Alternatively, the upper lobe bronchus may be encircled and divided at this point,
Fig. 4.3. One of the most important concepts in pulmonary surgery is visualization of the anatomy in three dimensions. Much of the dissection may be done from behind or the posterior aspect of the hilum. Here the bifurcation between the bronchus intermedius and upper lobe bronchus is being dissected and the upper lobe bronchus skeletonized. There is the constant finding of a lymph node at this “crotch.” Incision at the bifurcation and elevating the lymph node out of the area reveals the pulmonary artery within the fissure. Inset. Once the bifurcation is dissected the bronchus may be encircled. Superiorly, if the artery has been dissected the bronchus may be taken at this point.

which allows complete visualization of the artery from “behind” the fissure. This is the preferable move when there is nodal involvement in the fissure that makes dissection on the artery difficult. The arterial branch to the posterior segment of the upper lobe is adjacent (superior) to the superior segmental branch and occasionally may arise from this branch (Fig. 4.5). The arterial supply to the middle lobe usually arises just opposite the takeoff of the superior segmental branch. There is usually one middle lobe arterial branch, but two branches are not uncommon.

Resectability must be assured prior to dividing any vascular structures. The ability to remove all disease, including mediastinal lymph node disease, if encountered, must be clear. It offers the patient no benefit to proceed with resection if gross disease is left behind. There is no advantage to a palliative resection, only the disadvantage of the risk of the procedure. At times the surgeon must be prepared to be somewhat creative in completing a resection especially if the tumor involves the hilum of the lung and obscures the origin of the lobar vessels making individual dissection of these vessels impossible. Clamping the artery proximally allows the portion of the arterial wall containing the origin of the branches to be excised and the arterial wall either sutured primarily or patched with a piece of pericardium. Otherwise, proximal involvement of the pulmonary artery may mandate pneumonectomy but parenchymal conservation should always be considered as long as oncologic principles are not compromised. Rarely should proximal tumor involvement or encasement of the right upper lobe bronchus in and of itself mandate pneumonectomy as long as the surgeon is familiar with the technique of sleeve resection. The arterial trunk to the anterior and apical segments is divided between ligatures, preferably silk because of the easy handling and tying features of this material. The ties must be placed so as to leave enough distance between them to allow the branch to be divided and leave a cuff of artery on each side. No upward traction should be exerted when tying since the artery may be easily disrupted at the origin of the segmental branch. Usually, a single tie is placed on an arterial branch but a suture ligature may also be placed adjacent to the proximal tie for added safety. To avoid any accidental pulling on a tie, each suture is cut after the knot is complete and prior to dividing the ligated arterial branch. How much force one exerts when securing a knot on a pulmonary arterial branch is critical to avoid injury to the vessel. Only enough force to feel the intima “crunch” should be applied and no more. The pulmonary artery is a low pressure system which does not mandate a huge amount of force to ligate a vessel. More force than is necessary may result in avulsion of the arterial branch. Alternatively, a vascular staple may be used to divide the apical-anterior arterial branch. Once this branch is divided the origin of the upper lobe bronchus is readily apparent. Lymph nodes lying along the bronchus are dissected upward to be removed with the specimen, a maneuver which completes the dissection around the bronchus.

The superior pulmonary vein is divided either with a vascular stapler or tied and suture ligated (Fig. 4.6). Alternatively, a vascular clamp may be placed and the divided vein closed with a horizontal mattress stitch, the clamp removed, and the suture run as a simple stitch anterior to the mattress stitch back to where it was begun. Once the vein is divided the continuation of the pulmonary artery is identified as it lies posterior to the vein. The middle lobe arterial branch is readily visualized from the anterior aspect of the hilum and, to facilitate division of the fissure and separation of the middle lobe from the upper lobe, the branch should be mobilized.
for a short distance. The arterial branch to the posterior segment of the upper lobe at times may be seen through this anterior exposure or an additional anterior segmental branch may be identified. Once the artery is identified from this anterior approach and the middle lobe artery is seen, the minor fissure, which is usually incomplete, may be divided with an application of a linear stapler.

The posterior segmental branch of the artery is ligated and divided within the fissure. With the lung again retracted anteriorly the origin of the upper lobe bronchus is well seen and a stapler is used to close the bronchus (Fig. 4.7). The bronchus is taken as close as possible to its origin without compromising the lumen of the right main stem bronchus. The bronchus is divided and the upper lobe removed if the minor fissure has been divided. If the minor fissure remains it is completed with a firing of the linear stapler. In order to obtain definitive staging information, a complete mediastinal lymph node dissection should be performed.

Following division of the minor fissure and removal of the right upper lobe the middle lobe is left without tether since the oblique fissure usually is relatively complete. Postoperatively this situation may predispose to torsion and infarction of the middle lobe. In order to prevent this very significant complication the middle lobe is “reattached” to the lower lobe either by placement of several absorbable sutures placed in a figure-of-eight fashion or by placing a row of staples between the two lobes. The middle lobe must be properly oriented prior to attaching it to the lower lobe.

There are several potential pitfalls to avoid when performing a right upper lobectomy. For the most part it is one of the most straightforward of the pulmonary resections but problems may occur. The middle lobe vein must be identified and preserved when dividing the superior pulmonary vein. Once the superior pulmonary vein has been divided, great care must be taken to avoid injury to the middle lobe artery especially when dividing the minor fissure. Traction exerted on the upper lobe while it is still attached to the middle lobe by the intact minor fissure may result in an avulsion injury to the middle lobe artery. As already mentioned, the right main bronchus may be narrowed if the upper lobe bronchus is closed and subsequently divided with a stapler placed too close to its origin. This usually occurs when the lobe is retracted upward tethering the main stem bronchus prior to placing the stapler. If the main stem bronchus has been narrowed it is best to proceed with a sleeve resection and reanastomosis instead of trying to “repair” the damage. Waiting for a stricture to become symptomatic creates far more problems in the long run.

Right Middle Lobectomy

Middle lobectomy is thought by many to be the most difficult lobectomy because of the problems presented by the fissures. This is an erroneous concept since it is possible to accomplish the bronchovascular dissection and division from an anterior approach if the fissures are problematic. The middle lobe is a common site for inflammatory disease and bronchiectasis. It is a common location for mycobacterial infections other than tuberculosis (MOTT).

The illustrations (Figs. 4.8-4.10) depict the view from the left side of the table, the ideal position from which to operate. If the major fissure is well developed and the pulmonary artery is visualized easily within the fissure, the overlying pleura is incised. If the artery is not visible, the fissure overlying the artery must be divided in order to identify the artery. This creates air leaks and is generally messy and time consuming. To proceed with this “standard” approach, significant dissection in the fissure is required and it is safest to gain proximal control of the pulmonary artery by incising the hilar pleura overlying the main pulmonary artery with the lung retracted posteriorly. Within the fissure the middle lobe arterial branch is identified as it originates from the main pulmonary artery usually just opposite the branch to the superior segment of the lower lobe (Fig. 4.5). Most commonly, there is a single-arterial branch to the middle lobe but occasionally two branches are identified. The arterial supply to the middle lobe is ligated
Fig. 4.5. View of the pulmonary artery from within the fissure showing the position of the arterial branch to the posterior segment of the upper lobe in relation to the middle lobe branch and the superior segmental branch. If the fissure is well developed, the overlying pleura may be incised and dissection carried down directly on the vessel. If the fissure is poorly developed, it is easier to divide the bronchus, identify and divide the posterior segmental branch, and then complete the fissure with several firings of the linear stapler.

Fig. 4.6. Proximal control of the artery has been obtained by placing an umbilical tape around the artery. The superior pulmonary vein, with the middle lobe vein left intact, is divided between rows of vascular staples. Here the stapler is being applied to the vein.

with silk ligatures and divided. Once the arterial supply is divided, the middle lobe bronchus may be seen lying deep to the artery and slightly inferior, as viewed from within the fissure. The bronchus is dissected back to its origin from the bronchus intermedius, stapled, and divided. Alternatively, the bronchus may be divided and closed with interrupted sutures of braided or monofilament absorbable material of size 3-0 or 4-0.

With the lung retracted posteriorly, the anterior hilar pleura over the superior pulmonary vein is incised. The middle lobe venous tributary or tributaries most commonly drain into the superior pulmonary vein but can drain into the inferior vein on rare occasions (Fig. 4.1). To assure that a tributary is coming from the middle lobe, the lobe may be grasped with a lung clamp and retracted laterally (upward toward the incision). This will avoid division of small branches coming from the upper lobe. The venous branch is then divided after ligating with silk ligatures and securing with a suture ligature.

Once the bronchovascular structures have been divided the minor fissure is completed with a firing of the linear stapler. The anterior portion of the major fissure is likely well developed and is easily completed and the lobe removed.

An alternative technique for middle lobectomy is also illustrated and is likely to be more useful and versatile. This technique does not rely on the pulmonary artery being visible within the fissure and does not require extensive dissection in the fissure to identify the artery. The lung is retracted posteriorly. The hilar pleura overlying the superior pulmonary vein is incised and the middle lobe vein identified. The vein is ligated and divided and immediately posterior and slightly superior to the vein lies the middle lobe bronchus (Fig. 4.8). The bronchus is surrounded by connective tissue that is divided taking care to coagulate any bronchial arterial branches that are encountered. The bronchus should be followed back to its origin at the bronchus intermedius. The middle lobe arterial branch lies just posterior and slightly superior to the middle lobe bronchus but may not be visible prior to dividing the bronchus. The bronchus is encircled with a right-angled clamp staying close to the bronchial wall to avoid damage to the adjacent arterial branch (Fig. 4.9). The bronchus is divided with a scalpel using a right-angled clamp as a guide. The bronchial stump is closed with interrupted sutures. Alternatively a stapler may be applied to close the middle lobe bronchus.

Following division of the bronchus, the middle lobe arterial branch is easily seen and is circumferentially mobilized (Fig. 4.10).
The arterial branch or branches are ligated and divided. Once the bronchus, artery, and vein are divided, the minor fissure as well as the portion of the oblique fissure in contact with the middle lobe is divided with several firings of the linear stapler and the lobe is removed. A mediastinal lymph node dissection is then completed in order to obtain the most accurate and complete staging information.

Despite the apparent simplicity of middle lobectomy as described, there are several potential trouble spots. The middle lobe bronchus originates from the bronchus intermedius at essentially a right angle and is quite fragile and susceptible to injury. The origin of the middle lobe bronchus is not easily seen from the anterior approach and the bronchus intermedius may be damaged when the middle lobe bronchus is taken with a stapler. The middle lobe arterial supply may also present problems if there is more than one branch. Sometimes, the additional branch may be obscured and injured if its presence is not recognized. Care must also be taken when encircling the middle lobe arterial branch from the anterior approach in order to avoid injuring the main pulmonary artery within the fissure.

**Right Lower Lobectomy**

Because of the close proximity of the bronchovascular structures of the middle lobe, resection of the right lower lobe provides several unique challenges and is one of the more difficult lobectomies. Similar to the middle lobectomy, the pulmonary artery must be identified within the fissure in order to complete the resection and in those cases where the fissure is poorly developed, a direct attack through parenchyma often proves to be quite challenging. The chest is entered through either a standard posterolateral thoracotomy incision (5th intercostal space) or a vertical axillary muscle-sparing incision (4th intercostal space). If disease is noted within the fissure or if the hilum is involved it is safest, in my opinion, to obtain control of the proximal right main pulmonary artery. The hilar pleura is incised anteriorly and superiorly with the lung retracted posteriorly and the proximal pulmonary artery is encircled just lateral to the superior vena cava.

If the fissure is reasonably well developed, the pleura overlying the pulmonary artery is incised and the dissection is carried down onto the plane of the artery (Fig. 4.11). The branch to the superior segment of the lower lobe is first identified and the middle lobe arterial branch is most commonly found arising from the opposite aspect of the artery just across from the superior segmental origin. The dissection may be extended posteriorly along the superior aspect of the branch to the superior segment, which leads to the bifurcation of the upper lobe bronchus and bronchus intermedius. With the lung retracted anteriorly, the pleura overlying this bifurcation posteriorly is incised and a linear stapler encompassing the parenchyma within the fissure may be inserted from just above the superior segmental arterial branch through the area of the bifurcation. This move is possible since there are no vascular structures present posterior to the origin of the superior segmental arterial branch. On the superior aspect of the artery just opposite the superior segment the posterior segmental branch, the so-called recurrent branch (posterior segmental), to the upper lobe arises and is easily visualized. Rarely, this branch to the upper lobe may arise from the superior segment branch to the lower lobe but this possibility should be kept in mind. The posterior aspect of the major fissure is then divided and completed.

The relationship of the superior segmental branch to the middle lobe arterial branch determines whether the lower lobe artery may be divided as a complete trunk or whether the superior segmental branch and basal arterial trunk need to be taken separately. As illustrated in Figure 4.11 the superior segmental branch must be taken separately to avoid damage to the middle lobe arterial supply. The dotted line indicates the position for division of the basal segmental trunk. This is usually a 1- to 2-cm trunk and should be double ligated with a suture ligature or divided with a linear vascular stapler. The simplest stapling maneuver utilizes the endoscopic linear stapler with a vascular cartridge for closure and division (inset, Fig. 4.11). The stapler may be placed obliquely to include the superior segment branch while avoiding the middle lobe artery.

Dividing the pulmonary artery reveals the bronchus that lies just deep (medial) to the artery. With the artery retracted...
Chapter 4: Right-Sided Pulmonary Resections

Right-Sided Pulmonary Resections

49

Fig. 4.8. View of the right hilum from the left side of the table. The superior pulmonary vein has been dissected out and the middle lobe vein identified, ligated, and divided. The ligated stump of the middle lobe vein is seen. Immediately posterior to the vein lies the middle lobe bronchus. Usually, the bronchus has to be divided to have optimal visualization of the middle lobe artery, but at times the artery is seen slightly superior and posterior to the bronchus. Division of the bronchus facilitates division of the artery and provides the exposure to assess if there are other middle lobe arterial branches.

superiorly, the origin of the middle lobe bronchus may be visualized and the location for division of the lower lobe bronchus established (Fig. 4.12). The middle lobe artery lies superficial and superior to the middle lobe bronchus. Care must be taken to avoid compromising the origin of the middle lobe bronchus when stapling or dividing the lower lobe bronchus (inset, Fig. 4.12).

The bronchus may be closed either with a stapler or divided with a scalpel and closed with interrupted absorbable sutures.

With the lung retracted toward the apex of the chest, the inferior pulmonary ligament is divided up to the level of the inferior pulmonary vein (Fig. 4.13). An inferior pulmonary ligament lymph node (level 9) should be excised for staging purposes. The inferior pulmonary vein is dissected and encircled in preparation for division. A finger is passed around the vein after entering the appropriate dissection plane and the vein is divided with a vascular stapler (inset, Fig. 4.13). Alternatively, the vein may be clamped, divided, and sutured with a running monofilament thread, or doubly ligated prior to division. At the minimum a tie and a suture ligature are placed to secure the vein. The anterior aspect of the major fissure is now easily completed with a firing of the linear stapler that allows the lobe to be removed.

It is a common misconception that right lower lobectomy is difficult because of the necessity to identify the pulmonary artery within the fissure. If a “difficult” fissure is encountered, it is always best to obtain proximal control of the right main pulmonary artery as the initial maneuver. The artery may then be followed distally beyond the middle lobe branch that leads up to the fissure and facilitates dissection of the fissure minimizing air leaks. Alternatively, the artery may be identified posteriorly from within the crotch formed by the bronchus intermedius and the upper lobe bronchus and the posterior aspect of the fissure completed. Once the artery is identified further dissection within the fissure proceeds expeditiously. Rarely, it is necessary to dissect through the depths of the fissure to identify the artery. In my opinion there is no such thing as a “difficult fissure.”

BILOBECTOMY

Occasionally, the location of a lesion will mandate removal of the middle and lower lobes, a procedure which can be accomplished en bloc because of the common origin of these lobes from the bronchus intermedius. A tumor originating in the bronchus intermedius usually requires removal of both lobes but a lower lobe lesion that involves the external aspect of the lobar bronchus may also mandate taking the middle lobe. Where an indication exists for bilobectomy, the vascular supply for each lobe is isolated and divided as described for each individual lobectomy. Once the pulmonary arterial branches have been divided the point of division of the bronchus becomes obvious; the bronchus should be divided above the origin of the middle lobe bronchus just distal to the origin of the upper lobe bronchus (Fig. 4.14). Morbidity and mortality for bilobectomy exceed that for lobectomy alone; so this resection should not be performed solely for ease or convenience. The middle lobe should never just be assumed to be

Fig. 4.9. The middle lobe bronchus is encircled with a right-angled clamp and divided with a scalpel. It is important to identify the origin of the middle lobe bronchus to avoid damage to the bronchus intermedius. The bronchial stump is closed with interrupted absorbable sutures or alternatively a stapler may be placed and the bronchus closed. Note the relationship of the middle lobe artery to the bronchus.
Section I: General Thoracic Surgery

Fig. 4.10. Following division of the middle lobe bronchus, the arterial branch (or branches) is well seen and can be mobilized and divided (hatched line). Once the artery is taken the minor fissure is divided with a linear stapler, as is the anterior portion of the major fissure.

Fig. 4.11. The pulmonary artery within the fissure has been identified and dissected. The position of the branch to the superior segment is such that it must be ligated and divided separately from the rest of the arterial supply to the lower lobe. The superior segmental branch is shown here being encircled by a right-angled clamp and the point of division of the basal arterial trunk is marked (hatched line). Note the position of the superior segmental branch relative to the middle lobe artery. Inset. The basal arterial trunk is shown being divided by the endoscopic vascular stapler that both ligates and divides. The angle is usually ideal for placement of this stapler, which provides an extremely secure closure of three parallel rows of staples.

Postoperative Mortality

Thirty-day mortality from pulmonary resections is approximately 4%. Lobectomies and lesser resections have mortality between 1% and 2% while pneumonectomies still carry a mortality of 6% to 7%. The mortality rate is directly proportional to increased age, associated diseases, and the extent of resection. Respiratory complications, not surprisingly, are the most common cause of postoperative mortality in patients undergoing pulmonary resection. Cardiac complications also account for a significant percentage of mortality while technical problems such as hemorrhage, bronchopleural fistula, and empyema account for a small but significant percentage of complications leading to death.

Postoperative Morbidity

Approximately 30% of patients undergoing pulmonary resection will sustain a postoperative complication of which approximately two-thirds are minor and the other one-third nonfatal major complications. The most common complication is supra-ventricular arrhythmia that occurs in up to 20% of patients, depending upon how closely patients are monitored. Most of these respond to simple pharmacologic manipulation and rarely are hemodynamically expendable. The bronchial stump placed so close to the upper lobe bronchus may be at somewhat increased risk for breakdown compared to other bronchial closures.

Lesions within the bronchus intermedius often present additional problems for the surgeon. These tumors may invade the inferior pulmonary vein occasionally with proximal extension into the left atrium. Careful exploration is mandated to assess resectability prior to dividing any structures. Proximal involvement of the inferior pulmonary vein need not preclude resection if the vessel is able to be encircled or if the extent of atrial involvement is not excessive. Some of these lesions may demand intrapericardial pneumonectomy because of the proximal involvement of the atrium. A sleeve resection of the main bronchus may also be performed if the proximal extent of the tumor involves the bronchus at the level of the upper lobe bronchus. The right main bronchus may be divided proximal to the upper lobe origin and the upper lobe bronchus severed at its origin. The middle and lower lobes together with a portion of main bronchus are removed and the upper lobe anastomosed to the open end of the main bronchus.
Fig. 4.12. The stump of the lower lobe pulmonary artery is retracted superiorly to expose the lower lobe bronchus. The middle lobe bronchus that comes off the bronchus intermedius at a 90-degree angle must be identified and preserved. If a stapler is to be used, it must be placed in such an orientation as to avoid compromising the orifice of the middle lobe bronchus. The site of bronchial division is shown (hatched line). The bronchial division includes the bronchus to the superior segment as shown. Occasionally, it is necessary to close and divide the superior segment bronchus separately. Inset. A stapler is placed across the lower lobe bronchus distal to the origin of the middle lobe bronchus. Often the stapler has to be oriented in an oblique fashion to include the superior segment bronchus and avoid the middle lobe.

Fig. 4.13. With the lung retracted superiorly the inferior pulmonary ligament is incised up to the level of the inferior pulmonary vein. The vein is shown being dissected by incising the overlying pleura. The vein may then be encircled with a finger and divided between rows of vascular staples or clamped, divided, and sutured closed. Inset. The vein has been encircled and two rows of staples placed. The line of division is marked (hatched line). Often division of the vein precedes bronchial division, but there is no set order in which structures must be taken.
Section I: General Thoracic Surgery

significant at onset. With appropriate treatment the rhythm reverts to sinus quickly and patients may be taken off the antiarrhythmic drugs usually after 1 month. Other minor complications include postoperative air leaks lasting greater than 7 days and atelectasis. Major nonfatal events most commonly are respiration related with patients developing significant infiltrates and pneumonitis. A small percentage of patients require reintubation in the postoperative period for respiratory failure usually related to the development of an infiltrate. There are no definitive predictors for postoperative pulmonary complications though significant risk factors for major complications include age > 60 years, FEV₁ < 2 L, weight loss > 10%, associated systemic disease, and extent of disease. Pulmonary complications can be minimized with meticulous attention to postoperative respiratory maneuvers including chest physiotherapy and preoperative teaching.

Other complications of pulmonary resection include wound infections, and disturbances in mental status especially in older patients. Notwithstanding our best efforts to avoid them, complications do occur. If recognized early many can be treated without sequelae. Meticulous attention to detail in all phases of management, preoperative, intraoperative, and postoperative goes a long way toward keeping problems to a minimum.

SUGGESTED READINGS

EDITOR’S COMMENTS

It is a pleasure to be able to comment on my co editor Larry Kaiser’s approach to right-sided pulmonary resections. It’s been a long time since I have done lung surgery but I certainly have had more recent involvement in lung transplantation. Dr. Kaiser gives an approach that demonstrates his experience at not only performing the operations safely but also treating complications. The technical focus of this chapter is clear and important to every level of reader.

I think the most important aspect from my standpoint is the approach to the dissection of the pulmonary artery. As Dr. Kaiser mentions there is no muscular wall, so the strength is all in the intima. The vessels don’t take a lot of traction or inappropriate dissection. He discusses the importance of complete dissection before trying to encircle the vessel. Certainly avoidance of complications is the key here for doing these operations with mortality as low as 1%.

ILK
INTRODUCTION TO LEFT-SIDED PULMONARY RESECTIONS

Left-sided resections have a number of unique features distinct from those carried out on the right. The aortic arch is a left-sided structure and its position relative to the pulmonary artery and the left main bronchus is the major defining feature of resections on this side. Access to the proximal left main bronchus and carina is limited because of the aortic arch. Thus the left paratracheal region, a lymph node-bearing area, is difficult to access at thoracotomy. There is no well-defined area where a lymph node dissection is carried out as on the right side. Lymph nodes are dissected from the aortopulmonary window and the subcarinal space and, at times, from the paratracheal area.

Access to the most proximal aspect of the left main pulmonary artery, literally at the level of the pulmonary artery bifurcation, may be gained by dividing the ligamentum arteriosum. The left recurrent laryngeal nerve is highly vulnerable to injury because of its position in relation to the inferior aspect of the aortic arch. This nerve originates from the vagus nerve as it traverses the aortic arch and then “recurs” around the ligamentum arteriosum. Any dissection in the aortopulmonary window places the left recurrent laryngeal nerve at risk of injury.

The left main bronchus also varies significantly from the right. On the left there is a long segment of main stem bronchus prior to the bifurcation of the lobar bronchi as opposed to the right where the right upper lobe bronchus originates within 2 cm of the carina. Sleeve resection of either the upper or lower lobe is certainly feasible though left-sided sleeve resections account for only a minority of these resections in any series.

The lingular segment is analogous to the middle lobe in that it has separate pulmonary arterial supply and venous drainage as well as a distinct bronchus. Lingular segmentectomy was one of the first segmental resections described likely because of its well-defined, discrete bronchovascular anatomy.

Contralateral mediastinal lymph node involvement is much more common with left-sided lesions particularly lesions of the left lower lobe. For that reason, mediastinoscopy or other pathologic staging of the mediastinum is particularly important when assessing lesions of the left lower lobe.

SURGICAL TECHNIQUE

Left Upper Lobectomy

In the realm of pulmonary resections the left upper lobectomy is, perhaps, the most technically challenging. The location of the pulmonary artery in relation to the aorta and the branching pattern of the left pulmonary artery contribute to the technical difficulties. There are a number of potential pitfalls that must be avoided in order to safely complete a left upper lobectomy. Lymphatics from the left upper lobe commonly drain to lymph nodes in the aortopulmonary window (level 5) or paracarotid location (level 6), and these lymph nodes must be removed in order to obtain complete staging information. Despite the classification of these nodal locations as mediastinal (N2), involvement of these lymph nodes with tumor in the absence of other nodal disease is associated with a better prognosis than N2 disease in any other location. Survival with isolated involved level 5 or 6 lymph nodes approximates that of patients who have only N1 lymph node involvement (approximately 40% at 5 years) as long as a complete resection is able to be performed. Access to the superior mediastinum is difficult from the left side because of the location of the aortic arch in relation to the left main bronchus and tracheobronchial angle. For this reason, mediastinoscopy is extremely useful for left-sided lesions even without enlarged lymph nodes present on the CT scan since it allows accurate sampling of the paratracheal area in a manner that is significantly simpler than trying to access this area during thoracotomy. Needle aspiration of left paratracheal and tracheobronchial angle lymph nodes with the aid of endoscopic tracheobronchial ultrasound (EBUS) guidance in some hands may provide equivalent staging information.

Left upper lobectomy is begun by incising the hilar pleura anteriorly and superiorly with the lobe retracted posteriorly. The pulmonary artery emerges from beneath the aortic arch and is located superior and posterolateral to the superior pulmonary vein. The apical segmental branch of the superior pulmonary vein may cross the artery partly obscuring the apical-posterior segmental trunk of the pulmonary artery necessitating division of the venous branch first (Fig. 5.1). The appropriate plane of dissection on the pulmonary artery is entered proximal to the takeoff of the first branch and careful circumferential dissection is carried out. The left main pulmonary artery is safely encircled with the index finger and a blunt-tipped C-clamp is directed toward the encircled finger to allow an umbilical tape to be passed around the vessel. A Rumel tourniquet is placed but not snared to allow the main pulmonary artery to be occluded should it prove necessary. The superior pulmonary vein is dissected and encircled taking care to include the lingular branch. The vein may be doubly ligated or stapled with a vascular stapler and divided. It is both safe and expeditious to employ vascular staplers to ligate and divide both pulmonary veins and arteries. Parallel rows of staples are placed and the vessel is divided. Alternatively, the endoscopic vascular stapler that cuts between parallel rows each with three layers of staples may also be used.

The apical-posterior segmental branch of the pulmonary artery is a short, broad vessel that may be easily avulsed or torn if too much traction is applied when
retracting the lobe (Fig. 5.1). This is a dreaded complication of left upper lobectomy, which may force a pneumonectomy depending on the extent of the injury. If proximal control of the artery has not been secured, as discussed above, there exists a possibility for a particularly disastrous complication. Trying to get around the left main pulmonary artery in order to place a clamp on the vessel is extremely difficult when at the same time it is necessary to staunch the ongoing hemorrhage from the injury to the artery. Often a significant amount of blood is lost during this maneuver. One should avoid the temptation to wildly try to place a clamp on the vessel. Without encircling the vessel this results in, at best, only partial occlusion and, at worst, further injury to the vessel. Proximal extension of a tear in this portion of the pulmonary artery may result in an irreversible situation with the patient dying from exsanguination. If an injury to the artery occurs and proximal control has not been obtained, one should gently occlude the rent with a finger and assess the situation. It is difficult at best to attempt to suture the pulmonary artery without first gaining proximal control. Attempts to place sutures in the artery under these conditions may result in further injury to the artery as the torrential bleeding does not allow enough visualization to accurately place the sutures. It may be best to open the pericardium to secure additional length of the artery and encircle the artery within the pericardium for proximal control while maintaining the digital pressure on the arterial rent. Once proximal control is achieved, the branch is completely divided and the artery repaired with 5-0 or 6-0 monofilament, nonabsorbable sutures. Rather than avulsion of the apical-posterior arterial branch, a more common traction injury is a hematoma in the vessel from an intimal tear. The intima is the structure responsible for the integrity of the pulmonary artery; so this has the potential to be a disastrous situation. Proximal control should be obtained and the branch vessel ligated preferably proximal to the intimal tear. Placing a ligature at the area of the tear may result in complete avulsion of the branch when the knot is placed. As noted, it is best to recognize that this arterial branch presents special problems and avoiding problems with the pulmonary artery is far better and simpler than having to repair the artery no matter how good you may be at getting out of trouble.

Dissection on the artery continues distally following the artery toward and into the fissure. The left main pulmonary artery resides in an epibronchial location relative to the left main bronchus (Fig. 5.2). As the fissure is entered, the anterior segmental arterial branch to the upper lobe is encountered just proximal and opposite to the origin of the superior segmental branch to the lower lobe. Once the superior segmental branch is identified, the posterior portion of the fissure may be completed with a stapler. The anterior segmental branch is divided between silk ligatures (Fig. 5.3) and the artery is followed further distally until the lingular branches are encountered. There may be a single lingular trunk or two separate branches. The lingular branches are ligated and divided and the anterior portion of the fissure is completed with a firing of the linear stapler (Fig. 5.4). Alternatively, the fissure may be taken following division of the bronchus when it is all that remains holding the lobe in place.

Within the fissure the artery is bluntly reflected inferiorly away from the underlying bronchus, which is located medial (or deep) (Fig. 5.5). The bifurcation of the left main bronchus is visible at this point and care should be taken to avoid damage to the lower lobe bronchus when the upper lobe bronchus is divided. The bronchus needs to be skeletonized and encircled prior to its division. Bronchial vessels should be either electrocoagulated or occluded with metal clips and divided, depending on their size. It should not be assumed that the stapler used to close the bronchus will occlude these vessels. Staplers used on the bronchus are not particularly hemostatic because of the size (3.5 or 4.8 mm) of the staples. To avoid postoperative bleeding from a bronchial artery these vessels should be identified and ligated prior to dividing (or stapling) the bronchus.

Exposure of the left upper lobe bronchus is achieved either from both the anterior aspect of the hilum or from within the fissure. Division of the superior pulmonary vein exposes the bronchus as seen when viewing the hilum from the anterior aspect. After dividing the superior pulmonary vein, there is adequate exposure to work on cleaning off the bronchus and sweeping any lymph nodes upward with the specimen.
Chapter 5: Left-Sided Pulmonary Resections

55

Incising the fibrous tissue on the plane of the bronchus at the level of the bifurcation also facilitates division of the anterior portion of the fissure. The thumb and first finger placed at the bifurcation may be used to thin out the parenchyma in this location so as to be able to divide the fissure by firing the linear stapler after placing it through the hole formed by the opposed thumb and forefinger.

The upper lobe bronchus is stapled and divided as close as possible to the bifurcation (Inset, Fig. 5.5). Alternatively, the bronchus may be divided with a scalpel (open technique) and closed with individual sutures of either a 3-0 or 4-0 monofilament or braided nonabsorbable material (Fig. 5.6). The bronchus is divided in an open fashion, that is, incised with a scalpel in the presence of endobronchial disease that may be close to the bronchial margin since the stapler, by virtue of its width, obscures what otherwise might be an adequate margin. The importance of a negative margin is obvious and a frozen section of the bronchial margin should be obtained whenever an endobronchial lesion is present if not routinely for all but small peripheral lung cancers. The bronchial stump is checked under saline to assure that the closure is airtight. The anesthesiologist is asked to inflate the lung and hold a pressure of between 25 and 30 cm H₂O.

The inferior pulmonary ligament is incised freeing up the lower lobe, which it tethers though the value of this maneuver is questionable. The intent of incising the so-called inferior pulmonary ligament is to allow the lower lobe to more adequately fill the residual space following removal of the upper lobe. Lymph nodes in the paraaortic (level 6) and aortopulmonary window (level 5) locations are taken. The subcarinal space is opened by incising the mediastinal pleura posteriorly and just inferior to the main bronchus. Small vagal branches going to the lung are divided between metal clips. The contents of the subcarinal space (level 7) are removed using blunt and sharp dissection along with the liberal use of metal clips. The left paratracheal and tracheobronchial angle lymph nodes are most easily sampled at mediastinoscopy but if exposure of these nodal locations is required, it is obtained by dissecting inferior to the aortic arch heading medially. The pulmonary artery must be retracted inferiorly to permit this dissection, which is facilitated by dividing the ligamentum arteriosum (Fig. 5.7). On the left side there is not as well-defined a packet of superior mediastinal lymph nodes that yields a nice distinct packet of lymph nodes as is found on the right side. The nodes must be removed individually. Great care must be taken to avoid the left recurrent laryngeal nerve that “recurs” around the ligamentum arteriosum. If the patient is hoarse in the postoperative period, the vocal cords should be examined with a laryngoscope to assure that the left vocal cord is moving. If the
Section I: General Thoracic Surgery

Fig. 5.4. The anterior aspect of the fissure is taken with the linear stapler after the artery has been identified and dissected. A right angle clamp is around a lingular arterial branch in preparation for ligation and division of the branch.

Fig. 5.5. The pulmonary artery is retracted inferiorly to expose the origin of the left upper lobe bronchus. The point of division of the bronchus is shown (hatched line) just proximal to the bifurcation. The lingular bronchus and upper lobe proper are easily seen. Inset. The stapler is applied to the bronchus proximal to the lingula and upper lobe proper bifurcation. This is done from within the fissure.

Left Lower Lobectomy

In contradiction to the left upper lobectomy, left lower lobectomy can be one of the most straightforward pulmonary resections and is an excellent resection for those just beginning their experience in pulmonary surgery. The anatomy is quite well-defined and there are only a few traps into which one may be led. Again the role that mediastinoscopy plays in lesions of the left side, particularly left lower-lobe lesions, must be emphasized. Carcinomas of the left lower lobe involve contralateral mediastinal lymph nodes more commonly than lesions in any other lobe because of the almost constant occurrence of lymphatics that cross the midline. For left lung lesions, mediastinoscopy is not only the definitive invasive procedure for sampling right paratracheal lymph nodes but also provides access to the left paratracheal (level 2) and tracheobronchial angle (level 4) lymph nodes. The left-sided lymph nodes are actually easier to access with the mediastinoscope than at thoracotomy because of the location of the aortic arch relative to the left main bronchus. In experienced hands EBUS-guided needle aspiration biopsy of the left-sided lymph nodes may substitute for mediastinoscopy.

The chest is entered through either a standard posterolateral thoracotomy incision (5th intercostal space) or a muscle-sparing vertical axillary incision (4th intercostal space). Even for lower lobectomy there is no advantage to being in a lower intercostal (6th) space since the left vocal cord is paralyzed, the patient’s ability to cough and clear secretions in the postoperative period is markedly impaired and aspiration with subsequent pneumonia becomes a significant risk. Paralysis of the left vocal cord may not become apparent until several days after the operation because of edema of the vocal cord allowing for adequate glottic closure.

A variation of the standard left upper lobectomy is a lingular-sparing upper lobectomy that is useful in patients with borderline lung function where the primary tumor is in the apical or posterior segment of the upper lobe. Lesions in the anterior segment sometimes are amenable to this approach as well. Basically the dissection proceeds as for a standard left upper lobectomy but the lingular branch of the superior pulmonary vein is preserved as are the lingular arterial branches as they are identified in the fissure. The dissection on the bronchus is carried further distal than for standard upper lobectomy to identify the bifurcation between the upper lobe proper and the lingular bronchus. The lingular bronchus is spared as the stapler is applied to the upper lobe proper bronchus. The parenchyma is either “stripped,” as described classically for segmentectomy, or divided with a stapler guided by the location of the remnants of the distal ends of the bronchovascular structures and the anterior segmental arterial branch.
position of the hilar structures remains constant though intuitively one would have a tendency to think that if the fifth space is used for upper lobectomy the sixth must be appropriate for lower lobectomy. The pleural space is thoroughly explored to rule out visceral or parietal pleural spread of tumor, to assess lymph node involvement, to assess nodal disease within the fissure, and to establish whether left lower lobectomy is the procedure of choice. It is safest, especially for the less-experienced operator, to begin the dissection with the upper lobe retracted posteriorly to allow access to the proximal pulmonary artery, which is exposed by incising the pleura anteriorly and superiorly and dissecting down onto the artery. The appropriate plane is entered and the artery is encircled with a finger, an umbilical tape is passed, and a Rumel tourniquet is placed but not cinched down. This establishes proximal control if needed, a maneuver which is much easier to carry out at this point than at a time of sudden hemorrhage if the pulmonary artery or one of its branches is entered inadvertently.

If the fissure is near complete, that is, if the pulmonary artery is visible from within the fissure, dissection may begin in the fissure by incising the pleura overlying the pulmonary artery to enter the appropriate plane on the vessel (Fig. 5.8). Once this plane is reached, dissection may proceed in both an anterior and posterior direction along the artery. The superior segmental arterial branch is identified usually just opposite the lingular branch. This branch often needs to be divided separately depending on its location, relative to the lingular branch (Inset, Fig. 5.8). At times the basal segmental trunk of the artery may be divided along with the superior segmental branch but this is dependent on the superior segment branch coming off distal (i.e., inferior) to the takeoff of the lingular branch. The artery to the lower lobe may be taken with a vascular stapler or doubly ligated. The linear endoscopic vascular stapler is ideally suited for ligation and division of the basilar arterial trunk. Once the superior segmental branch of the artery is identified, the posterior portion of the fissure may be completed by incising the pleura overlying the pulmonary artery posteriorly just before the artery enters the lung parenchyma. There are no branches coming off the inferior aspect of the artery posterior to the superior segment branch and a finger may be inserted along the artery between this branch and the posterior aspect of the lung. This allows for placement of a linear stapler and completion of the fissure. Rarely should it be necessary to directly cut into lung parenchyma overlying the artery in order to complete a fissure. Likewise, the anterior aspect of the fissure may be completed with the linear stapler once the artery has been identified.

The inferior pulmonary ligament, a fibrofatty band tethering the lower lobe medially, is incised using electrocautery and divided up to the level of the inferior pulmonary vein (Fig. 5.9). The inferior pulmonary vein may be visualized from either the anterior or posterior aspect of
the hilum and is encircled with a finger or right angle clamp once the plane of dissection is entered. The vein is then ligated and divided with a vascular stapler (Inset, Fig. 5.9), or clamped and sutured.

By retracting the proximal pulmonary artery stump superiorly the bronchus to the lower lobe is identified (Fig. 5.10). The bifurcation of the left main bronchus will be seen with this maneuver confirming its identity. Care must be taken to include the superior segmental bronchus with the division of the lower lobe bronchus. This may require division of the bronchus in a slightly oblique orientation and this should be done as close as possible to the bifurcation. Identification of the lower lobe bronchus is also facilitated following division of the inferior pulmonary vein as the bronchus lies just posterior and superior to the vein. This identification may be helpful when there is lymph node involvement or tumor within the fissure, making it difficult to approach the bronchus from that aspect.

A lymph node dissection is performed by taking the contents of the aortopulmonary window (level 5), the para-aortic location (level 6), and the subcarinal space (level 7). The subcarinal space is entered by retracting the lung anteriorly and incising the pleura just inferior to the left main bronchus posteriorly. Several vagal branches are encountered going to the lung, which need to be clipped and divided. The contents of the subcarinal space are removed with the aid of metal clips placed on the small bronchial vessels. An inferior pulmonary ligament lymph node (level 9) is also taken. This is most often encountered as the inferior pulmonary ligament is incised and is usually found near the inferior pulmonary vein.

**SUGGESTED READINGS**

Fig. 5.10. The pulmonary artery is retracted superiorly to reveal the lower lobe bronchus. The line of division (*hatched line*) is just proximal to the bifurcation between the superior segment bronchus and the basilar segmental bronchus. The line of division needs to be slightly oblique to encompass the origin of both of these. Most commonly the bronchus is closed with a stapler, but it may also be cut and sutured closed.

**EDITOR’S COMMENTS**

Clearly, there are major differences in the pulmonary anatomy on the left side. The techniques are well described and the figures are clear.

I think the most important issue that Dr. Kaiser has raised here is what happens if the left pulmonary artery is injured. It is clear that sewing the vessel in a bloody field is nearly impossible. What is extremely important is the ability to open the pericardium and gain proximal control. This obviously is a technique well used in vascular surgery and it can't be over-emphasized in this situation. This is the difference between a surgical mortality and a benign postoperative course. He also emphasizes the importance of cutting the inferior pulmonary ligament and filling the entire chest cavity. These are basic principles in lung surgery but can't be emphasized enough.

ILK
Pneumonectomy, defined as the removal of an entire lung, is technically one of the easiest operations and yet one of the riskiest operations performed in the chest. This risk is inherent to the final result of the procedure—having only one lung. Elective pneumonectomy when performed for nonsmall-cell lung cancer (NSCLC) has an operative mortality that ranges from 3% to 12%. This is significantly higher than that for an elective coronary artery bypass grafting. Unlike other paired organs that are removed for malignancy, the lungs are unusual in the fact that a right-sided pneumonectomy has a significantly higher operative risk than a left. The indication for pneumonectomy affects the operative risk as well. When a pneumonectomy is performed for a destroyed lung from an inflammatory process such as tuberculosis, the reported operative mortality is higher and ranges from 3% to 30%. The morbidity from this has been quoted as high as 44%. In this chapter, we focus on pneumonectomy for NSCLC and do not discuss the specific issues and considerations of pneumonectomy for mesothelioma, for destroyed lung, or other less common clinical scenarios. Finally, since many regard a pneumonectomy as a disease in and of itself, a surgeon rarely should go into an operation planning to do a pneumonectomy. Parenchymal preservation should always be front and center in the mind of the surgeon and a pneumonectomy should be done only if there exists no other way to completely remove all of the cancer and achieve negative margins. There are several different types of pneumonectomies. These various types are only mentioned for reasons of completeness but the description of most is out of the scope of this chapter.

**TYPES OF PNEUMONECTOMIES**

There are several different types of pneumonectomies with the most radical being extrapleural pneumonectomy, defined as the removal of the entire lung along with the ipsilateral pleura, hemidiaphragm, and hemipericardium. This type of operation is most commonly done on patients with mesothelioma. Other types of pneumonectomy include completion pneumonectomy, which is removal of the entire remaining lung after a patient has had some other portion of that lung removed at a previous operation. There are also intrapericardial and extrapericardial pneumonectomies. The former is often performed for anatomic reasons such as for large central tumors. A carinal pneumonectomy refers to the removal of an entire lung in addition to the carina. This requires an anastomosis between the remaining main stem bronchus and the distal trachea. This chapter focuses only on the surgical techniques of a standard pneumonectomy.

**INDICATIONS FOR PNEUMONECTOMY**

Prior to taking any patient to the operating room for a possible sleeve resection and/or what might turn out to be a pneumonectomy, the patient’s pulmonary function tests and cardiovascular status must be carefully assessed and a decision rendered regarding suitability. In addition, a pneumonectomy for a presumptive malignancy should never be performed until tissue confirmation has been obtained. Often the inability to perform a parenchymal-sparing resection is discovered intraoperatively; so the preoperative evaluation should always include an assessment of the patient’s ability to tolerate a pneumonectomy. This possibility should be discussed with the patient preoperatively. The thoracic surgeon and the patient must weigh the risks and benefits of pneumonectomy, including increased morbidity and mortality and decreased exercise tolerance against the benefit of potential cure and increased survival.

We perform a cardiac stress test and an echocardiogram on all of these patients. Reversible cardiac ischemia is a contraindication to elective pneumonectomy; therefore, a thorough evaluation of the patient’s cardiac status must be undertaken. Patients should have areas of reversible myocardial ischemia revascularized and/or cardiologic clearance prior to elective pulmonary resection. On echocardiogram, the presence of a patent foramen ovale should be known preoperatively and significant valvular disease assessed and corrected if severe.

The baseline pulmonary function and the extent of the planned resection help guide the surgeon. Historically, there have been multiple articles proposing lower limits of various pulmonary function study variables below which operative risks become prohibitive. These limits should be used only as guidelines. However, a decision must be made for each patient on an individual basis. The old teaching that the FEV₁ must be 800cc or greater at the completion of a pulmonary resection is obsolete. This old surgical dictum obviously does not take into account the size of a patient. An FEV₁ of 800cc for a four-and-three-quarter-foot tall, thin female is more than adequate. Thus, the percent predicted FEV₁ (FEV₁%), which takes into account the various shapes and sizes that patients come in, is a much better representation. The percent postoperative predicted (popFEV₁%) and percent postoperative predicted diffusion capacity of the lung for carbon monoxide (popDLCO%) have been shown to be reliable predictors of postoperative morbidity and mortality. These values should be calculated with the aid of a quantitative perfusion lung scan when patients have radiologic evidence of segmental, lobar, or greater areas of atelectasis. Important studies have shown that when the popFEV₁% is less than 40, and the popDLCO% is less than 40, the operative risks are significantly increased. These values are guidelines since each patient and clinical situation is different.

Another important assessment besides the popFEV₁% and the popDLCO% is the arterial blood gas measurement. The presence of significant hypercapnia raises an important red flag. When the preoperative arterial blood gas, a mandatory test prior to possible pneumonectomy, shows a PaCO₂
of 48 mmHg or greater the operative risk is significantly increased. We have even lowered this in our practice to 45 mmHg. However, the surgeon and patient again must decide together before operation as to what will be done if a sleeve resection with parenchymal sparing is not technically feasible or if after the completion of a sleeve resection a positive bronchial margin is identified.

Finally, since a pneumonectomy is associated with an increased risk compared to a lobectomy, certain oncologic principles need to be considered. The presence of residual or calcificant N2 disease (after neoadjuvant therapy for biopsy-proven N2 disease) in, in our opinion, an absolute contraindication for pneumonectomy (except in certain young patients with high popFEV1% and popDLCO% or those who are having significant hemoptysis, etc.). Once the decision has been made to perform a sleeve lobectomy or pneumonectomy, the operation should follow certain principles and be carried out in a certain sequence.

**THE SURGICAL PROCEDURE: RIGHT-SIDED PNEUMONECTOMY**

Despite the fact that there have been vast improvements in the field of general thoracic surgery and anesthesia, a pneumonectomy done today is not much different from the one done 30 years ago, except perhaps for the advent of stapling devices. After preoperative staging with the use of integrated positron emission tomography (PET)/computed tomography (CT) scan and CT scan, along with a careful assessment of the cardiopulmonary reserve, and the establishment of the absence of N2 disease via mediastinoscopy, transesophageal ultrasound with fine needle aspirate, or VATS, the patient is finally prepared for pneumonectomy. Preoperative bronchoscopy is performed and occasionally that alone can tell a surgeon that a pneumonectomy is required to achieve an R0 (negative margin) resection. If a lesion is attached (not invading, but attached) to the right proximal bronchial wall and one is able to get distal to it with the bronchoscope and it continues as one contiguous lesion down into the bronchus intermedius and into the right lower lobe, then right pneumonectomy is the only appropriate procedure. One must be sure that it is not simply tumor thrombus coming out of the right lower lobe bronchus, but rather is tumor adherent to the bronchial main stem wall. Similarly, if a lesion is quite large and involves the main pulmonary artery on the right and courses distally involving branches of the basilar pulmonary artery, a right pneumonectomy is required. Otherwise, in the vast majority of patients a sleeve resection should be the desired approach and the decision to do a pneumonectomy is not made on preoperative bronchoscopy, but rather on surgical exploration.

After the preoperative bronchoscopy the appropriate devices are placed—epidural catheter for postoperative analgesia (place prior to anesthesia), a double-lumen endotracheal tube (placed by the surgeon if there is a large and/or bloody lesion in the proximal airway to avoid any blood from spilling into the soon-to-be-only lung), an arterial line, central line, warming blanket, and serial compression devices on the legs. The patient is turned onto the left lateral decubitus position, carefully padded, and secured. There are several types of possible surgical approaches including a vertical axillary thoracotomy, and so on, but we focus on the most common approach for a pneumonectomy, a posterolateral thoracotomy. This can be performed in several ways as well, but we prefer cutting about half of the posterior aspect of the latissimus dorsi muscle, sparing all of the serratus anterior muscle and entering the chest over the uncut, unshingled, and unbroken sixth rib. We also strongly believe that an intercostal muscle flap should be harvested in any patient who is going to undergo a sleeve lobectomy or possible pneumonectomy (as shown in Fig. 6.1) for use either in covering a bronchial stump or wrapping around a bronchial anastomosis. We have demonstrated the usefulness of this pedicled graft in over 400 patients. It should be harvested and mobilized prior to the placement of a chest retractor. This provides a well-vascularized, soft, pliable muscle that is free of periosteum that does not calcify over time when harvested in this manner. It can reach to buttress any bronchus and it provides a barrier between sleeve pulmonary artery and/or bronchus though it should not be circumferentially wrapped around any anastomosis. It only takes a few minutes to mobilize and we have shown in a prospective randomized trial that it also is associated with a decrease in the pain of thoracotomy. If a sleeve resection is not performed, the muscle can then be tucked to the bronchus with use of interrupted sutures as shown in Figure 6.2.

Once the rib spreader is placed, the chest is explored and carefully inspected to rule out pleural effusion that could be consistent with T4 disease, metastatic nodules on the pleura or diaphragm that could represent M1 disease, or previously nonimaged pulmonary nodules. We prefer to remove all the mediastinal (N2) lymph nodes and perform a complete systematic thoracic lymphadenectomy as opposed to simple nodal sampling. If any of the N2 nodes look or feel suspicious or were imaged by CT and/or integrated
fluorine-18 fluorodeoxyglucose (FDG)-PET-CT as suspicious and were not ruled out as harboring cancer prior to thoracotomy, frozen section analysis should be performed. Once the decision has been made that resection is the appropriate option, the lung is retracted posteriorly and the anterior hilum is exposed. The hilar pleura is incised posterior to the phrenic nerve. The superior pulmonary and the inferior pulmonary vein are dissected free. Lymph nodes from this area are removed and the small veins that lead to the phrenic nerve are carefully coagulated so as not to injure the nerve since a functional phrenic nerve is important even following pneumonectomy. In rare situations, a single right pulmonary vein is found that makes a sleeve resection more difficult because the blood has to be baffled back into the left atrium. The inferior pulmonary ligament should have already been released during the inspection phase to allow removal of the level 9 and 8 lymph nodes. The inferior pulmonary vein is then easily encircled with an index finger as shown in Figure 6.3. If the subcarinal lymph nodes have been completely removed, this move is facilitated since the finger is placed in between the superior pulmonary vein and middle lobe vein and then comes around anterior to the right main stem bronchus. Dissection is then carried anteriorly and more superiorly. Since a sleeve resection is usually attempted first, we often isolate the superior pulmonary vein next, depending on the size and location of the tumor and remove the N1, level 10, and level 11 lymph nodes. Very commonly, there is a large hilar lymph node that interdigitates between the superior aspect of the superior pulmonary vein and the main pulmonary artery just as it courses distally to the superior vena cava. If one is able to completely remove this large N1 node, the course of the distal main pulmonary artery becomes visible. This makes encircling the superior pulmonary vein safer and easier. The vein is carefully encircled around its posterior aspect so as not to injure the main pulmonary artery that runs just beneath it. If the tumor is large and proximal, the pulmonary artery may have to be encircled as the initial maneuver. At times it may be necessary to obtain control of the intrapericardial portion of the right main pulmonary artery. The pericardium should be opened away from the phrenic nerve,
which must be visualized and spared. Opening the pericardium allows central inspection to assess resectability and allows for proximal control of the vessels. However, the intrapericardial mobilization may increase the incidence of postoperative atrial fibrillation (AF). A finger is then used to encircle the main pulmonary artery and the superior pulmonary vein.

The sequence of ligation of the hilar structures is highly dependent on the position of the lesion and the surgeon’s preferences. Prior to taking any vessels, we have shown in a nonrandomized but prospective trial that giving 250 mg of Solu-Medrol may help prevent the complication of postpneumonectomy pulmonary edema (PPE). Thus, we recommend giving this 5 to 10 minutes prior to ligating the vessels. One should also test clamp the pulmonary artery for a minute or two and ensure that the patient’s hemodynamics tolerate the shunting of all of the pulmonary blood supply into the left lung. If the patient’s blood pressure drops quickly and if the clamp or the fingers/hand used to clamp the pulmonary artery is not compressing the heart, this suggests that the patient will not tolerate a pneumonectomy. This move should be repeated several times, but if it continues to occur the vessels should not be taken and the operation should be aborted. This is a very rare occurrence but is a final check of the patient’s suitability for pneumonectomy. In this situation, despite the careful preoperative evaluation that suggested that the patient was a candidate for pneumonectomy, the procedure cannot be carried out.

There is little data that documents the advantage or disadvantage of taking the vein prior to the artery. Kurusu has reported an oncologic advantage in taking the vein prior to the artery because it may prevent the accidental dislodgement of cancer cells into the systemic circulation during the manipulation and dissection of the tumor. Others believe there is less blood lost in the removed lung when the vein is taken after the artery. There is no data to support these latter claims. However, if a pneumonectomy (or lobectomy) is performed robotically, there is distinct advantage to taking the vein last. This prevents engorgement of the specimen. If the lung to be removed becomes swollen from early vein ligation, it leads to more bleeding from the specimen, less working room in the chest during minimally invasive surgery, and more difficulty in manipulating the specimen from one side to the other.

If a thoracotomy is the chosen surgical approach then the vessels can also be ligated in several different ways. We prefer to take the vein with a vascular stapler that staples and cuts simultaneously, but prefers to take the artery with a vascular stapler that only staples. The staplers disperse the closure of the vessel over its entire length as opposed to bunching it up into one suture ligature. Another method involves clamping the artery, cutting, and then oversewing the end with a running Prolene suture (Ethicon, Cincinnati, Ohio) along its length. This obviously takes longer to do.

Once the vessels have been cut, the bronchus is the only remaining structure that is keeping the lung in vivo. We prefer not to take the bronchus first on a right or left pneumonectomy as we often do on a right upper lobectomy because it is easier to achieve a short stump if the bronchus is taken after the vessels are divided. However, on the right side the bronchus can be taken prior to the vessels if needed to obtain better access to the pulmonary artery. It can make the dissection easier for large anterior tumors that are too big to allow for anterior dissection of the hilar structures. It can be taken with a knife or a stapler (we use 4.8-cm-long staples) before the artery or veins or divided. If taken with a knife, one can visualize the trachea and ensure the position of the double-lumen tube. If taken with a stapler, one should ask the anesthesiologist to inflate and then deflate the balloon on the tracheal cuff side after closing the stapler but before firing the instrument to ensure that the tracheal balloon of the double-lumen tube has not been entrapped. Either way a short stump is a crucial and mandatory part of a successful right pneumonectomy.

We divide the azygous vein first with a vascular stapler prior to stapling the right main stem bronchus. One must ensure the central venous line is not in the azygous vein. It is usually very easy to see the blue tip of the central line in the superior vena cava or even in the azygous vein. In rare situations when an intercostal muscle is not available and if there is no pericardial fat pad, the azygous vein can be used as a form of bronchial coverage. This is accomplished by dividing the vein as far posteriorly as possible and then ligating the other end tied flush against the superior vena cava. The vein is cut as distally as possible and this provides a long flap of a defunctionalized vein that can be split and used to cover the right main stem bronchus. We frequently use this technique for a radical extrapleural pneumonectomy for mesothelioma because the intercostal muscle is not useable as it may be infiltrated with tumor cells. It is important to note that a pleural flap does not provide adequate coverage since it is paper thin and is often nonviable within 48 hours after surgery.

Once the pulmonary vessels have been ligated and divided, the bronchus is taken last. The lung is retracted so the right main stem is exposed. If all of the subcarinal lymph nodes have been dissected and the large bronchial artery that comes from the undersurface of the carina to the subcarinal nodes has been clipped, the left main stem bronchus is already exposed. A stapler is placed (more easily on the right than on the left because of the absence of the aortic arch on the right in most patients) and fired flush with the trachea. As described above, one must ensure that there are no parts of the double-lumen tube in the staple line and that no suction catheters are within the bronchus before stapling and cutting. Although there is some literature about handsewing the bronchus, there is no real data that suggests that handsewing is better than stapling or vice versa. We recommend the stapling technique.

The bronchial margin should be sent for frozen section analysis as should the artery or vein margin if the tumor is close. The chest is then filled with warm water, not saline. We prefer the former because of the oncologic possibility that it may lyse tumor cells that are floating in the chest. Also it is easier to see through it than saline to check the stump for a leak. The double-lumen tube should now be opened to both chests and the stump is tested. If a bronchial leak is noted, nonabsorbable monofilament sutures are placed under the staple line in a vertical mattress fashion with knots opposite the pulmonary artery. The bronchial closure should be interrogated again to assure that there is no stump leak. The intercostal muscle flap is then set in place to cover the entire bronchus (as shown in Fig. 6.2). The sutures that are placed in the bronchus should be small superficial bites so as not to injure the stump or its blood supply. The entire stump is covered. We have used this method to cover the bronchus after lobectomy and main stem bronchus after pneumonectomy in over 500 patients, including over 100 who have had preoperative radiation and have had only two BPFs.

We prefer leaving a chest tube in the postpneumonectomy space mainly to monitor postoperative bleeding but also to allow for setting the mediastinum. The best way to handle the postpneumonectomy space has never been described. Some surgeons recommend aspirating the air out with a syringe after the chest has been closed, just prior to leaving
the operating room. Others recommend placing a chest tube and rolling the patient on his or her back after the operation is completed, and then removing it prior to going to the recovery room. We prefer leaving it in overnight on water-seal only to assess for postoperative bleeding. We attach the tube to a conventional pleural drainage system and place a sign on it that reads "NO SUCTION." This avoids errors postoperatively. A special "pneumonectomy"-balanced drainage system is also available and we have come to prefer it, but first aspirate the air out of the space just prior to connecting to the chest tube.

After a pneumonectomy, the mediastinum shifts over time toward the operated side and this shift can cause serious problems such as postpneumonectomy syndrome, which is described later in this chapter. We believe it is best to have the trachea just to the left of the midline after a right pneumonectomy, since the remaining left lung will slowly displace the trachea toward the pneumonecctomy space.

The chest is closed after the placement of a chest tube using intracostal sutures to decrease pain as shown in Figure 6.4.

**THE SURGICAL PROCEDURE: LEFT-SIDED PNEUMONECTOMY**

The oncologic and physiologic principles for a left pneumonectomy are the same as for a right. However, because the anatomy is different, some special considerations must be mentioned. The left pulmonary artery is shorter than the right. The ligamentum arteriosum tethers the left main pulmonary artery. This structure can be divided to access the most proximal portion of the left main pulmonary artery if necessary but it is not necessary for a standard left pneumonectomy. Routinely this should be avoided since the left recurrent laryngeal nerve is wrapped around this structure and may be injured when the ligament is divided. Because of the short left main pulmonary artery, intrapericardial dissection is more commonly needed on the left than on the right. If a patient has had a previous coronary artery bypass procedure, great care must be taken to avoid injuring the left internal mammary artery and the vein grafts during the pneumolysis phase of a left pulmonary resection. Once the decision has been made that a left pneumonectomy is indicated (the patients is N2 negative, a sleeve is not possible, etc.), the dissection starts, as on the right, by incising the hilar pleura reflection. The avascular plane between the pleural reflection and the pericardium is dissected and the inferior and superior pulmonary veins are identified. Again, the phrenic nerve must be avoided. As described on the right side, the inferior pulmonary ligament is released and the level 9 inferior pulmonary ligament lymph nodes are removed in addition to the level 8 periesophageal and the level 7 subcarinal lymph nodes. If this is done it, becomes easy to get a finger between the inferior pulmonary vein and the left main stem bronchus and encircle the inferior pulmonary vein with a vessel loop (as shown in Fig. 6.5). A finger can be used to get around the superior pulmonary vein as well, but prior to doing this, the edges of the vein must first be dissected free. Care must be taken when dissecting between the superior edge of the pulmonary vein and the inferior border of the left main pulmonary artery being certain to avoid the anterior-apical trunk of the left pulmonary artery. Additionally, the superior pulmonary vein lies anterior to the left main stem bronchus. Large proximal tumors with extraluminal disease can present difficulty when attempting to encircle the vein. Occasionally, the bronchus can be taken first; however, on the left side especially, we prefer taking the bronchus last since it is much more difficult to achieve a short bronchial stump on the left than on the right because of the position of the aortic arch relative to the trachea. Once the superior pulmonary vein is encircled (as shown in Fig. 6.6), a loop is placed around it and the pulmonary artery is mobilized just distal to the ligamentum. The index or middle finger can be placed around it to fully mobilize the vessel. It should be test clamped and the patient’s hemodynamics observed as described on the right side. Once all three vessels are encircled, we favor giving 250 mg of intravenous Solu-Medrol and test clamping the artery as described above. The veins and artery are taken as described on the right side leaving the left main stem bronchus.

The biggest difference between a right and left pneumonectomy probably is the position and length of the bronchus. The left main stem bronchus is the longer of the two main stem bronchi and its location with respect to the aortic arch makes it more difficult to achieve a short bronchial stump. A short bronchial stump is
a mandatory part of a pneumonectomy as it keeps the incidence of a BPF low by preventing the pooling of secretions and likely remains better vascularized. The best technique involves pulling the lung up and aggressively retracting it out of the chest. In order to do this, the pericardial reflection must be taken off of the left main stem bronchus. Often there may be a piece of a subcarinal lymph node left that was not completely removed in the lymphadenectomy portion of the case. The remainder of that node should be removed to allow for optimal visualization of the left main stem bronchus. Care must be taken on the left side, as on the right, not to impinge on the opposite side main stem. The tracheal balloon of the double-lumen tube can distend the membranous part of the opposite main stem bronchus, which is paper thin. This can be injured as the subcarinal lymph node is swept off of the opposite chest’s main stem. Once the entire left main stem is seen and its junction with the trachea visible, a stapler is carefully slid under the arch. The stapler is fired, the bronchus is cut, and the specimen is removed. As described on the right side, the bronchial margin should be examined on frozen section and the stump checked for a leak with a water submersion test. When taken properly, the left main stem bronchus will immediately retract well under the aortic arch. It should be difficult to see and it should be covered by the surrounding mediastinal structures. This reduced exposure is probably a factor for the lower incidence of a BPF on the left compared to the right, though we still recommend coverage with an intercostal muscle flap. To place these sutures in this short retracted stump one must retract the arch back carefully and avoid the pulmonary artery as well. The chest is closed after the placement of a chest tube using intracostal sutures to decrease pain. Although the operation is often straightforward, the postoperative course can be challenging. Keys to successful outcomes include fluid restriction, strict aspiration precautions, and aggressive pulmonary toilet and cardiopulmonary therapy.

**MANAGEMENT OF COMMON COMPLICATIONS AFTER PNEUMONECTOMY**

**Vocal Cord Dysfunction**

Because of the location where the left vagus nerve traverses, the aortic arch with the recurrent laryngeal “recurring” around the ligamentum arteriosum, one must be vigilant during the dissection in this area to avoid injury to the nerve. This is especially true when dissecting in the hilum for removing of the aortopulmonary lymph nodes. The right recurrent laryngeal nerve is at risk at the apex of the right chest when the mediastinal lymph node dissection extends up to the subclavian artery, around which the nerve “recurs.”

The reported incidence rate of vocal cord paralysis after thoracic interventions is relatively high, ranging from 4% to 31% for postoperative recurrent laryngeal nerve paralysis after primary thoracic cancer surgery. There is also an increased morbidity, as recurrent laryngeal nerve and vagus nerve injuries are associated with increased rate of reintubation, arrhythmias, and aspiration. Risk factors for recurrent nerve injury and vocal cord dysfunction include preoperative radiotherapy, left pneumonectomy, and pericardiectomy.

Mechanism of injury varies and can be caused by heat, stretch devascularization,
or direct transection. Heat injuries usually result from using the electrocautery for hemostasis in the vicinity of the nerve. Stretching of the nerve causing neuromyopathy occurs while dissecting out the hilum, especially when associated with a hilar tumor. The perineural vascular supply is delicate and can be injured easily during dissection. The anterior terminal branch of the recurrent nerve, designated as the motor branch, is located laterally, a position which makes it particularly vulnerable to surgical wound or trauma.

Symptoms of recurrent laryngeal nerve injury on either side include hoarseness, aspiration, poor cough, and dysphagia. Diagnosis is made based on symptoms. When symptoms become apparent, a laryngeal examination should be done to confirm the diagnosis and be vigilant of the consequences such as aspiration, bronchial obstruction, pneumonia, and reintubation. On examination, recurrent laryngeal nerve paralysis results in fixation of the vocal fold in a nonmedian position and causes incomplete glottal closure. Treatment varies depending on the extent of injury. Patience is usually best since most injuries are not secondarily to severing of the nerve. The surgeon is usually aware if the nerve had to be cut to remove the tumor. If the nerve is still intact, the edema will usually resolve in several weeks and the voice will return to normal. If the nerve has been severed then medialization thyroplasty is indicated. If the nerve is preserved then most clinicians would recommend waiting 6 months before undertaking medialization thyroplasty. During that time functional voice and swallowing therapy is indicated. Often these patients will regain function of their recurrent laryngeal nerve with no need for further therapy.

Arrhythmias

Arrhythmias after pulmonary resection continue to be a frustrating and common problem. An incidence ranging from 5% to as high as 40% following pneumonectomy has been reported depending on how closely the patients are monitored and how it is defined. AF is by far the most common arrhythmia associated with pulmonary resection. Supraventricular tachycardia (SVT) and ventricular tachycardia (VT) are much less frequent than AF. The incidence of SVT following pneumonectomy is reported to be between 13% and 26%. Most arrhythmias occur within the first 2 to 3 days after operation and rarely later than postoperative day 5. The incidence is higher if an intrapericardial dissection has been performed.

The physiology and cause underlying these arrhythmias is poorly defined. Some studies have shown that an increase in right heart pressure and an increase in pulmonary vascular resistance predisposes a patient to clinically significant arrhythmias. Factors that have been associated with postoperative arrhythmias following pulmonary resection include hypoxia, intrapericardial dissection, pericardial manipulation, vagal irritation, pulmonary hypertension, older age, and preexisting cardiac or pulmonary disease. The prognostic significance of arrhythmias, especially AF, is difficult to determine because they are often associated with other more serious cardiac or pulmonary complications. There is no difference in mortality between patients who develop AF, not associated with other complications, who are appropriately treated following pulmonary resection than in those patients who maintain normal sinus rhythm. However postoperative arrhythmias increase the length of stay and thus the cost of the hospital stay.

The data suggests that prophylactic use of an antiarrhythmic drug perioperatively can decrease the incidence of AF in patients undergoing pneumonectomy. Historically, digoxin has been used to prevent and treat arrhythmias following pulmonary resection; however, there have been multiple randomized controlled trials demonstrating minimal to no effect. Prophylactic beta blocker administration has been shown in some studies to be effective in both prevention and treatment of postoperative AF, but its use after a pneumonectomy should be judicious. Amiodarone has been proposed for prophylaxis and is currently used by many to treat AF and SVT. A prospective trial using intravenous amiodarone following pulmonary resection was stopped due to the increased incidence of adult respiratory distress syndrome (ARDS). Amiodarone has been proposed for prophylaxis and is currently used by many to treat AF and SVT. A prospective trial using intravenous amiodarone following pulmonary resection was stopped due to the increased incidence of adult respiratory distress syndrome (ARDS) following pneumonectomy. There have, however, been other studies demonstrating that prophylactic use of oral amiodarone resulted in a decrease in the incidence of SVT when compared to placebo with no reported increase in ARDS. Magnesium sulfate infusion postoperatively has been shown in one randomized trial to be an effective agent in reducing the incidence of AF. The most commonly used drugs at this time for both prophylaxis and treatment of AF/SVT are calcium channel blockers. We prefer a calcium channel blocker, specifically diltiazem that has been shown in multiple studies to decrease the incidence of postoperative AF/SVT when given both orally and intravenously. In a randomized controlled trial by Amar it was shown that postoperative SVT occurred significantly less in the diltiazem-treated group versus placebo. Specifically, a standard intravenous dose is given postoperatively on the day of surgery and subsequently converted to oral dosing on postoperative day 1. When a patient has any sign of an arrhythmia, underlying causes such as hypoxia, electrolyte abnormalities, and even silent myocardial ischemia must be ruled out. Symptomatic arrhythmias must be taken seriously and cardioverted when necessary. If the arrhythmia continues for more than 48 hours, the risks and benefits of anticoagulation and/or chemical or electrical conversion should be considered.

Postpneumonectomy Pulmonary Edema

Postpneumonectomy pulmonary edema (PPE) was first described by Gibbon in 1942 but not extensively covered in the literature until almost 40 years later. Currently no consensus exists with regard to the definition of the syndrome or ways to prevent its occurrence. It most commonly presents 12 to 96 hours postoperatively and can be confused with, or occur in combination with, any of the following: congestive heart failure, pulmonary thromboemboli, or ARDS due to sepsis, pneumonia, and aspiration, all of which make PPE a diagnosis of exclusion. Most authors agree that in order to make the diagnosis there must be progressive and refractory hypoxemia, pulmonary edema on chest imaging, and widened alveolar to arterial oxygen gradient following lung resection.

The incidence of this complication ranges widely due to a lack of a consensus definition. Reported incidences of PPE range from 4% to 7% but may be as high as 12% to 15% if less severe cases are included. The reported mortality also varies but is uniformly high, ranging from 50% to 75% and even 100% in a few studies. Risk factors are variable but generally include perioperative transfusion (result of an immunologic reaction similar to transfusion-related lung injury (TRALI)), higher ventilation pressures intraoperatively, right pneumonectomy (reportedly a result of poor lymphatic drainage), perioperative fluid overload, older age, poor perioperative lung function, preexisting cardiac disease, extensive lymphadenectomy, neoadjuvant therapy, and the hyperoxia, volutrauma, and hyperinflation associated with one-lung ventilation.

Histologic changes in PPE are almost identical to those that are well described in ARDS prompting some authors to suggest that they are one and the same. Initially
the endothelial integrity is lost with resulting extravasation and hemorrhage. Type I pneumocytes undergo necrosis and platelet/fibrin microthrombi form. After about 5 days organization and repair begins with the proliferation of fibroblasts and type II pneumocytes. Also during this time squamous metaplasia of the epithelium begins as well as hyaline membrane formation. Interstitial and alveolar fibrosis occurs at 10 days with widespread thrombotic, fibroproliferative, and obliterative changes occurring, along with extensive remodeling of the pulmonary vascular bed. As the process continues past 14 days, collagen deposition dominates the remainder of the disease process.

Often despite careful preoperative planning, intraoperative technique, and postoperative management, postpneumonectomy pulmonary edema occurs. Once it does occur, treatment is at best difficult and resource consuming. The successful use of nitric oxide has been reported. A precise mechanism, even with the knowledge of the histology, has never been clearly delineated, making prevention impossible. Treatment traditionally consists of fluid restriction, diuretics, and ventilator support. Similar to ARDS, PPE patients benefit from sedation and paralysis to improve oxygenation. Attempts should be made to keep peak airway pressures as low as possible using pressure-controlled ventilation and permissive hypercapnia. Positive end-expiratory pressure should also be used to keep the inspired oxygen concentration as low as possible.

We have described above the use of Solu-Medrol prior to pulmonary artery clamping. This assumes the steroid bolus helps reduce the ongoing and subsequent inflammatory cascade caused by the manipulation of the lung and sudden shift in pulmonary blood flow. Although these data are interesting there have been no large prospective randomized trials to date that either prove or disprove the utility of this intervention or elucidate potential complications.

Chylothorax

Chylothorax is often caused by leaking lymphatic ducts from dissection of malignant mediastinal lymph nodes. However, even with complete thoracic lymphadenectomy the incidence of chylothorax is very low. As opposed to esophageal resections, chylothorax following pulmonary resections, including pneumonectomy, is mainly due to injury to small branches of the thoracic duct and is rarely due to injury to the main duct itself. Those patients with N2 disease, especially with extracapsular N2 disease, carry an increased risk of developing a chylothorax, likely due to the obstruction of lymphatic channels by metastatic disease. The mortality rate in the literature after iatrogenic/traumatic chylothoraces ranges from 4.5% to 10%.

Chylothorax following pulmonary resection occurs more often on the right side. This is explained both pathologically and anatomically. Bronchogenic carcinomas occur more often on the right side (ratio of 6 to 4) thus leading to more frequent mediastinal lymph node dissections on the right. Anatomically, the lymphatic drainage of the lungs predominates in the right chest for two reasons: (1) the right lung is larger; (2) the lymph flow to the right paratracheal nodes from the left lung is greater than the lymph flow from the right lung to the left paratracheal nodes.

Initial management of iatrogenic chylothorax following pulmonary resection is predominantly conservative, using medium-chain triglyceride diets or occasionally total parenteral nutrition, as well as drainage via tube thoracostomy. There are a few nonsurgical treatments that have been reported for chylothorax. Lymphangiography can be used both for diagnostic and anatomic detail. There are some studies that report spontaneous closure of the defect following the procedure due to the beneficial effects of the iodinated contrast on the laceration (if small). Percutaneous catheterization of the thoracic duct with embolization of the defect has also been reported. Pleuroperitoneal shunting has been used permitting resorption of the chyle by the peritoneum; however, this procedure makes documenting closure of the defect difficult and is mainly reserved for postoperative pediatric patients and cases of nontraumatic malignant chylothoraces.

Surgical management is reserved for those patients that fail conservative measures. Prolonged drainage of a chylothorax leads to neutropenia and carries significant morbidity. Reexploration via thoracotomy and suture ligation of the main duct with fibrin glue placement is best. The main duct can also be ligated via a laparotomy or laparoscopic approach. No matter what treatment is used, the thoracic surgeon must be aware of the potential for severe protein malnutrition, dehydration, and immune deficiency due to large losses of lymphatic constituents, as the daily volume of the thoracic duct can approach 3 L. Prompt treatment is necessary after diagnosis and aggressive fluid and nutritional monitoring must be instituted. If conservative measures do not stop the leak within 5 to 7 days and if the output remains high (>800cc/day), surgical ligation of the duct is best.

Bronchopleural Fistula and Empyema

Postpneumonectomy BPF is defined as a communication between the main stem bronchial stump and the ipsilateral pleural space. It is a life-threatening problem because infected material can be aspirated into the only remaining lung. It is by definition associated with a postpneumonectomy empyema defined as the presence of purulent material in the postpneumonectomy space and is usually but not always associated with a BPF. When it occurs within the first 6 months after a pneumonectomy there commonly is a BPF associated with it. Early recognition and aggressive treatment with reoperation are the keys to survival.

The overall incidence of BPF and empyema is greater following pneumonectomy than after lesser resections. Following pneumonectomy, for any reason, the incidence of BPF/empyema ranges from 2% to 16%. When stratified by disease state, the incidence for empyema and BPF following pneumonectomy for primary lung cancer are 5.8% and 4.1%, for metastatic disease 3.1% and <1%, and for benign disease 24% and 9.9%, respectively. When it occurs, BPF
following pneumonectomy is associated with a mortality rate that ranges from 30% to 50%. Also noted is an increased incidence of BPF following pneumonectomy if operation has been preceded by neoadjuvant treatment. There is also an increase in both cardiac and pulmonary complications and a concomitant increased hospital stay and associated costs with the occurrence of a BPF. Multiple studies have identified both local and systemic factors that are associated with the development of empyemas and/or BPF following pulmonary resections. Local risk factors include the following:

1. Presence of carcinoma at the bronchial margin
2. Long bronchial stump
3. Disrupted bronchial blood supply
4. Technique of stump closure
5. Preexisting empyema
6. Extended resections
7. Preoperative radiation
8. Postoperative need for mechanical ventilation
9. Right versus left pneumonectomy
10. Right pneumonectomy following neoadjuvant therapy

Systemic factors include the following:

1. Poor nutritional status
2. Diabetes
3. Sepsis
4. Preoperative chemotherapy
5. Underlying lung disease (including chronic infection and COPD predicted by decreased pPpFEV₁ and pPdLCO)
6. Preoperative immunosuppression (steroid therapy)
7. Older age (>70 years)
8. Postoperative sputum positive for AFB

Prevention of postpneumonectomy BPF and empyema centers on attention to careful intraoperative technique. One must limit the length of the bronchial stump, which will help to prevent pooling of secretions leading to increased risk of infection at the site of bronchial closure. Perioperative prophylactic antibiotics have a well-known benefit following general thoracic procedures. For patients with preexisting infection/empyemas or the potential for significant pleural space contamination (destroyed lung or preoperative BPF) specific culture-directed antibiotic regimens may be indicated. There have been reports of intraoperative factors such as blood transfusion that are an independent risk factor for postpneumonectomy respiratory complications. Method of closure of the bronchial stump remains controversial in the current literature. There are a variety of studies that report the superiority of both handsewn and stapled closures. No matter what closure is chosen most authors suggest bronchial stump reinforcement following pneumonectomy, especially in cases where breakdown is more likely (neoadjuvant therapy, presence of infection, and right-sided procedures) is mandatory. As described above, we prefer an intercostal muscle flap. Other options are a pericardial fat pad, defunctionalized azygous vein flap, or a pleural flap.

In cases where postpneumonectomy BPF or empyema is suspected, early diagnosis is critical because the earlier it is diagnosed and treated the better the prognosis. Early empyemas without BPF, though uncommon, are best managed by debridement of the space. When the space has been sterilized, it should then be filled with antibiotic solution (a Clagett procedure) and the tubes removed. Although management of postoperative BPF remains a problem, immediate drainage of the pleural space can be a lifesaving procedure because it may prevent aspiration of accumulated fluid into the contralateral lung. A variety of treatment strategies have been proposed for subsequent management. For small fistulas (<3 mm in size) with a short stump occasionally tube drainage alone is sufficient along with the injection of fibrin glue into the fistula. Sometimes these small fistulas close spontaneously, but that is very rare. In those cases where tube drainage does not result in closure of the small BPF, some authors advocate the use of videoscopic drainage and debridement combined with bronchoscopic closure using cauterization or metallic coils with the application of fibrin glue. For larger BPFs attempts at endoscopic closure are not recommended.

Definitive surgery to close a postpneumonectomy BPF is quite involved and thus the patient’s medical and nutritional status must be optimized, the postpneumonectomy space must be clean and healthy, the need for postoperative mechanical ventilation minimized, and there must be no evidence of recurrent carcinoma. A variety of procedures have been used for bronchial stump closure following development of a large (3 mm or greater) BPF. The traditional, well-described procedure initially developed by Pairolero involved multiple debridesments, the use of muscle flaps or omentum to plug the fistula, and finally closure via a Clagett. Others have suggested a transternal, transcardial approach to the bronchial stump via the posterior pericardium and subsequent mobilization of the affected stump, reanastomosis, and a reinforced closure.

Postpneumonectomy Syndrome

Postpneumonectomy syndrome is an unusual complication occurring most often after right pneumonectomy. Resulting from an extreme shift and rotation of the mediastinum and contralateral lung into the empty pleural space, it produces symptomatic proximal airway obstruction and causes air trapping. The main stem bronchus is stretched and compressed against the vertebral bodies, descending aorta, and/or remaining pulmonary artery branches. Patients present months to years following pneumonectomy with dyspnea, stridor, and recurrent pneumonias. Chest radiographs and CT show an extreme shift of the mediastinal structures and bronchoscopy reveals severe proximal airway extrinsic obstruction and sometimes bronchomalacia. Other causes must be ruled out including recurrent malignancy, pulmonary hypertension, progression of underlying lung disease, pulmonary thromboembolism, and congestive heart failure.

Although it is impossible to predict, the syndrome is described mostly in children and young adults; however, there are occasional reports in the adult literature as well. Most surgeons attempt to prevent the acute shift of the mediastinum by avoidance of chest tubes following pneumonectomy, or if they are used, tubes are either clamped or left to water-seal drainage only. To correct the shift when it does occur, the mediastinal structures must be shifted back to a more anatomic location. This can be done via anterior pericardiorrhaphy, which anchors the pericardium to the parasternal chest wall and by placing expandable saline-filled breast implants into the postpneumonectomy space, which is usually spared of adhesions, stabilizing the mediastinum. However, these techniques have fallen out of favor for fear of infecting the pneumonectomy space. Tracheomalacia after long-standing obstruction is an indicator of poor outcome. Treatment is often the placement of silicone removable stent that helps keep the airway open.

SUGGESTED READINGS

Amar D, Roistacher N, Rusch VW, et al. Effects of diltiazem prophylaxis on the incidence and
The authors have provided a very complete review of pneumonectomy, a procedure that many say results in a disease in and of itself since it leaves one with a single lung that is the recipient of the entire cardiac output. If patients make it through the postoperative period without a significant complication, many will lead a reasonably normal life though with some limitation. Despite the fact that individuals can live a normal life with one lung, it remains our view that every effort possible should be made to conserve pulmonary parenchyma even if that means performing a sleeve resection of the main stem bronchus and resecting and reconstructing a portion of the pulmonary artery. Rarely if ever do I enter the operating room knowing that the operation is going to result in pneumonectomy, I am always thinking of what can be done to preserve pulmonary parenchyma. But there are situations where pneumonectomy is the only choice if a complete resection is to be accomplished. If the main pulmonary artery is involved so far resection is to be accomplished. If the main pulmonary artery is involved so far resection is to be accomplished. If the main pulmonary artery is involved so far resection is to be accomplished. If the main pulmonary artery is involved so far resection is to be accomplished. If the main pulmonary artery is involved so far resection is to be accomplished. If the main pulmonary artery is involved so far resection is to be accomplished. If the main pulmonary artery is involved so far resection is to be accomplished.

On the right side there are more options in terms of bronchial reconstruction and I have never implanted the main stem bronchus and reimplanted only the basal segments. Several points made by the authors raise some questions and areas of disagreement. The authors state that mediastinal lymph node involvement is an absolute contraindication for pneumonectomy while many of us would argue that it is not the case especially if there is a response to neoadjuvant therapy. That said, the incidence of complications in patients undergoing pneumonectomy who have received neoadjuvant therapy

(continued)
clearly is higher than in those who have not received any preoperative therapy. It certainly is our belief that patients who are candidates should be offered the therapy that offers the best opportunity at long-term survival and currently that is complete resection even in the face of N2 disease. Often the wisdom as to whether or not a given therapeutic intervention should have been carried out must be determined in retrospect. Subjecting a patient to a pneumonectomy that, even in the most experienced hands is associated with a mortality in the range of 5% to 10%, not to mention the potential for postoperative morbidity, may be said to have been ill-advised if the patient lives for less than 1 year following the procedure. Yet, currently there is no way to predict which patients will live for less than 1 year so that operation in that group could be avoided. Thus if a patient with documented N2 disease is otherwise a reasonable candidate for operation they should at least be considered for an aggressive treatment regimen that likely will include resection.

If a patient is being considered for pneumonectomy, it is probably reasonable to carry out a complete extent of disease evaluation to include brain imaging as well as combined CT/PET imaging. It is a travesty to subject a patient to the risks inherent in pneumonectomy only to find evidence of disseminated disease early in the postoperative period that could have been identified prior to operation saving the patient from an invasive procedure from which he/she will derive no survival benefit.

The authors have recommended the use of Solu-Medrol prior to dividing the pulmonary artery based on the thought that this steroid might prevent PPE. Currently no evidence exists to support this contention though admittedly it would be difficult, if not impossible, to mount a study to prove efficacy since the incidence of PPE, fortunately, is very low.

Despite the author’s recommendation to use distilled water, as opposed to normal saline, to irrigate the chest there exists no evidence that such a regimen results in any tumor cell lysis. If one wants to irrigate the pneumonectomy space prior to closure normal saline works just fine and is certainly more physiologic.

As the authors point out there are a number of ways to manage the pneumonectomy space in the immediate postoperative period. We prefer to place a chest tube in the space connected to a balanced drainage system (Pneumonectomy Pleur-Evac) that allows for the mediastinum to be “set” as well as monitors the amount of bleeding. The tube is removed on the morning of the first postoperative day. Connecting a tube that is within a pneumonectomy space to a standard drainage system that could inadvertently be connected to suction not only is dangerous but also could prove deadly. Simply placing a sign warning to not connect to suction is not enough precaution as far as I’m concerned. Aspirating the space with syringe and needle following chest closure also is acceptable as a maneuver to “set” the mediastinum but does not offer the opportunity to monitor postoperative drainage.

The authors discuss a number of other technical issues that bear some comment. The bronchial stump should be left as short as possible to promote healing that is not likely influenced adversely by “secretions collecting” but more by compromised vascularity if the stump is left too long. The incidence of recurrent laryngeal nerve injury cited by the authors seems high. Injury to the nerve should be uncommon since its anatomic location is well known. A patient presenting with paralysis of the left vocal cord caused by involvement of the recurrent nerve in the aortopulmonary window usually proves to have unresectable disease. Occasionally, tumor involves the nerve in a location where it can be resected thus sacrificing the nerve. Many patients have no difficulty with a paralyzed vocal cord even early following the injury but the major issue remains aspiration and inability to mount a productive cough to clear secretions. Vocal cord injection for augmentation is a reasonable temporizing procedure but there should be at least 6 months of observation before attempting a cord medialization procedure since most patients accommodate very well to unilateral vocal cord paralysis. Contrary to the author’s contention, rarely does nerve function return but the contralateral vocal cord allows for glottic closure by extending across the midline to effect cord apposition.

Postpneumonectomy empyema with or without bronchopleural fistula is a devastating complication though patients can be managed. An infected space without a fistula may only present with the patient losing weight and failing to thrive. There should be a low threshold for interrogating the space with thoracentesis to assess whether infection is present. An air fluid level associated with coughing up watery sputum should also prompt thoracentesis and drainage of the space initially with a chest tube. Definitive management requires an open window thoracostomy placed in a dependent location. Usually, adequate drainage allows for the bronchial fistula to close, but it may take months. Once the space is clean, transposition of a muscle flap and closure may be carried out. In our experience the Clagett procedure, where the space is filled with antibiotic solution and closed, works only rarely but in certain situations may be attempted. Transternal division and closure of the bronchus should be reserved for those cases with a very large leak that is unlikely to close on its own.

LRK
HISTORY
The first sleeve lobectomy was performed by Price-Thomas in 1947 for an endobronchial adenoma. Five years later, Allison reported a sleeve lobectomy for carcinoma. It was Paulson and Shaw, however, who popularized sleeve resection with their 1955 paper, entitled “Bronchial anastomosis and bronchoplastic procedures in the interest of preservation of lung tissue.” The use of their techniques allows the modern thoracic surgeon to perform parenchymal-sparing procedures, even in association with reconstruction of the PA (described for the first time by Allison and Thomas in the 1950s), on patients who would not tolerate a pneumonectomy. In the case of malignancy, sleeve resections may be performed without compromise of oncologic principles.

PRINCIPLES AND JUSTIFICATION
Pneumonectomy is associated with an increased morbidity and mortality when compared with lobectomy and sleeve lobectomy. Thus, in our practice, we make every effort to avoid pneumonectomy. This includes complex bronchoplastic and bronchovascular reconstructions when required. The justification of this approach is simply that by avoiding pneumonectomy we avoid its attendant risks while providing an equivalent cancer operation. In addition, lung-sparing procedures allow us to offer curative operations to patients with poor pulmonary function who would not otherwise tolerate the removal of an entire lung.

PREOPERATIVE ASSESSMENT AND PREPARATION
Our preoperative evaluation includes a complete history and physical examination. Special attention is focused on previous thoracic procedures and chest irradiation. The use of high-dose steroids or systemic illnesses that might interfere with bronchial anastomotic healing is noted. All patients have a chest X-ray, a chest computed axial tomography (CAT) scan, and pulmonary function testing with diffusion capacity. Patients with a diagnosis or suspicion of malignancy also have an extent-of-disease workup, which includes a bone scan and magnetic resonance imaging (MRI) of the brain when indicated.

We perform mediastinoscopy selectively in patients with malignant disease. Patients who have mediastinal adenopathy of >1.0 cm on CAT scan undergo mediastinoscopy before thoracotomy. If the mediastinoscopy is negative, we proceed with the thoracotomy. If the mediastinoscopy reveals ipsilateral N2 disease, patients are referred for preoperative chemotherapeutic or chemoradiation therapy and return later for resection. Those patients with contralateral N3 disease are referred for chemoradiation therapy and are not offered surgical resection.

ANESTHESIA
After induction of general anesthesia, all patients undergoing sleeve resection require bronchoscopy by the operating surgeon. This can be done with either a rigid or a flexible bronchoscope. Bronchoscopy allows visualization of the lesion and planning of the resection. After bronchoscopy, it is important for the surgeon to have a complete discussion with the anesthesiologist regarding the operative plan. If a right-sided sleeve resection is contemplated, a left endobronchial double-lumen tube should be placed (Fig. 7.1). If a left-sided sleeve resection is contemplated, a right endobronchial tube is placed. For sleeve pneumonectomy or a carinal sleeve resection, a sterile anesthesia circuit is required to allow direct ventilation from the surgical field.

OPERATIONS
We have performed sleeve resections through standard posterolateral incisions, serratus-sparing posterolateral incisions, and lateral incision, all of which are satisfactory for exposure and dissection.

After entry into the chest, complete exploration is carried out to rule out metastatic disease to either the pleura or lung parenchyma and to assess resectability. On both the right and left side, we begin our dissection in the anterior hilum and completely dissect out the main pulmonary artery (PA). Special care must be taken on the left side to avoid damage to the short left main PA and specifically the apical segmental arterial branch. If there is bulky disease or any difficulty is encountered with dissection, we do not hesitate to open the pericardium on either side to obtain proximal control. Next, we encircle the main PA with an umbilical tape to assure proximal control. The remaining steps are specific to the sleeve resection being performed and each will be described independently in what follows.

Right-Sided Resections

Right Upper Lobectomy Sleeve Resection: The Prototype Bronchoplastic Procedure
After proximal arterial control has been obtained, we continue our dissection superiorly and enter the plane of the right upper lobe bronchus (Fig. 7.2). The lung is retracted anteriorly, and we continue our dissection in the bifurcation between the right upper lobe bronchus and the bronchus intermedius. A “crotch” lymph node is a consistent finding in this location. This node is elevated away from the bifurcation to reveal the PA branch to the superior segment of the right lower lobe. Once this branch is identified, the posterior portion of the fissure is completed with a linear stapler. This approach avoids extensive parenchymal dissection in the fissure. The bronchus intermedius is circled just distal to the right upper lobe take-off, and an umbilical tape is placed to aid in dividing the airway at the appropriate time. Up to this point, we have not made

Bronchoplastic Procedures
Anna Maria Ciccone, Federico Venuta, Camilla Vanni, and Erino A. Rendina
any irreversible maneuvers. A complete inspection is carried out to ensure that all diseases including nodal disease can be removed. Once complete resectability is confirmed, we begin by ligating and dividing the PA branches to the right upper lobe. Similarly, the venous drainage is divided with a vascular stapler taking care to preserve the middle lobe venous drainage.

The minor fissure is completed with a linear stapler. The main stem bronchus is encircled at its origin, and an umbilical tape is placed. Before committing to the sleeve resection, it is often productive to divide the right upper lobe bronchus at its origin to see whether the tumor can be cleared with a negative bronchial resection margin. This is especially important with carcinoid tumors, in which the endobronchial component may be attached only at one point and the lesion simply pulled out leaving a clear bronchial margin. Once the bronchus has been opened, the decision to proceed with sleeve resection may be made based on the findings either grossly or microscopically.

To begin the sleeve resection, we divide the main stem bronchus with a No. 15 blade just proximal to the right upper lobe take-off. Similarly, the bronchus intermedius is divided just distal to the right upper lobe take-off (Fig. 7.3). For upper lobe sleeve resections, these cuts must be perpendicular to the long axis of the airway and placed between cartilaginous rings so as to result in a clean cut. An angled division of the bronchus is to be avoided. The proximal and distal airway margins are cut from the specimen and the true margin inked by the surgeon. We personally take the margins to the pathologist so that proper orientation can be demonstrated prior to frozen-section examination. Once we have documentation that the resection margins are free of tumor, the reconstruction is begun. Microscopic tumor present at a bronchial margin requires additional resection of the involved area or possibly pneumonectomy.

We perform the bronchial sleeve anastomosis in an interrupted manner. The key to a successful bronchial sleeve anastomosis is a pneumostatic well-approximated, tension-free repair that accounts for any size discrepancy between ends by precise suture placement. We do not take a “tuck” in the proximal airway to make up for a size discrepancy. Rather, we make up the size discrepancy along the entire circumference of the anastomosis by precise suture placement.

When performing an interrupted anastomosis, we use 4-0 oiled, absorbable, braided suture. The first suture is placed in an “outside-to-in” fashion at the junction of the cartilaginous and membranous bronchi. The suture is not tied but is secured to a suture guide. Additional sutures are placed at 2-mm intervals to complete the first half of the cartilaginous anastomosis (Fig. 7.4). Once the midpoint of the cartilaginous bronchus is reached, we begin tying the sutures starting at the corner. The surgeon “crosses” the next suture in the series to relieve tension while the assistant ties. The cartilaginous anastomosis is completed from the midpoint down to the opposite corner in a similar manner. The lung is retracted anteriorly to reveal the membranous portion of the bronchus. The membranous portion of the anastomosis is completed with interrupted sutures. The chest is filled with saline, and the anastomosis is tested to 20-cm water inflation pressure. Needle hole air leaks are ignored; however, air leaks between the cut edges of the bronchus, if small, are reinforced with simple interrupted sutures. A large area of leaking may require the entire anastomosis to be redone.

We wrap all anastomoses with intercostal muscle (Fig. 7.5), but occasionally we use an omental or pericardial fat...
Fig. 7.3. Division of the right main stem and bronchus intermedius during right upper lobe sleeve.

Flap. Although ossification of the intercostal muscle flap can occur, it does not necessarily cause problems; in fact, the bronchus has very limited intrinsic motility and a stable caliber. If the intercostal muscle flap is loosely applied around the bronchus, even if some retraction occurs, there is no reason why the hardening caused by ossification should produce stenosis. When the sleeve resection is planned preoperatively, the intercostal pedicle flap may be prepared before the insertion of the rib retractor to avoid crushing the intercostal vascular bundle, and is prepared at full thickness, encompassing a wide pleural flap. The flap is slid backward around the bronchial anastomosis, between it and the PA. The flap is then turned until its pleural side is in contact with the bronchial anastomosis, and the pleura is secured to the bronchus by interrupted sutures.

Middle Lobe Sleeve Resection
The middle lobe sleeve resection is an infrequently performed resection. After proximal arterial control, the middle lobe vein is identified, isolated, and divided (Fig. 7.6). The bronchus to the middle lobe lies immediately posterior to the middle lobe vein. The bronchus is followed back to its origin. A right-angled clamp is placed around the bronchus intermedius, and it is divided at a location proximal to the middle lobe orifice. The division is slightly angled. The distal division is also angled to preserve the orifice to the superior segment of the lower lobe. The PA lies directly posterior and slightly superior to the bronchus, and care must be taken to avoid injury when dividing the bronchus. After division of the airway, the middle lobe arterial branch is easily visualized. The branch is ligated and divided. Next, the minor fissure and anterior portion of the major fissure are completed with firings of a linear stapler.

After confirmation of negative margins, the airway anastomosis is performed in an interrupted manner as described previously for the right upper lobe sleeve resection. In performing a middle lobe sleeve resection, special consideration must be given to the superior segmental orifice of the lower lobe. One must avoid narrowing the orifice to the superior segmental bronchus when creating an anastomosis. An intercostal muscle flap is used to wrap the anastomosis to separate it from the PA.

Bilobectomy Sleeve Resection
Bilobectomy sleeve resection is performed for an endobronchial lesion in the bronchus intermedius that extends proximally toward the upper lobe orifice (Fig. 7.7). The basic principles of proximal arterial control, microscopic negative margins, and a precise tension-free anastomosis apply. Here the right main stem bronchus is divided just proximal to the right upper lobe take-off and the right upper lobe bronchus is divided at its origin. The right upper lobe bronchus is then anastomosed to the main stem bronchus after removal of the middle and lower lobes, the so-called “Y” sleeve. Due to the reorientation of the upper lobe bronchus after removal of the middle and lower lobes, special care must be taken to avoid torsion of the bronchus at the level of the anastomosis.

Left-Sided Resections
Left Upper Lobe Sleeve Resection
Proximal arterial control is obtained with care to avoid injury to the short apical-posterior segmental branch of the left PA. We continue our dissection along the plane of the artery and identify the superior segmental branch to the lower lobe (Fig. 7.8). At this point, we complete the posterior fissure with a linear stapler. The
anterior segmental artery is ligated and divided. The lingular branches of the PA are identified, ligated, and divided. The lung is retracted posteriorly, and the upper lobe venous drainage is divided with a vascular stapler. The anterior portion of the fissure is completed with a linear stapler. The only remaining attachment to the specimen is the bronchus. The main stem bronchus is encircled proximal to the bifurcation, and an umbilical tape placed to be used as a “handle.” Two 2-0 silk stay sutures are placed in the proximal left main stem and used for retraction. The main stem bronchus is divided proximal to the bifurcation, and the left lower lobe bronchus is divided at its origin. The origin of the superior segmental bronchus can be quite close to the origin of the lower lobe bronchus, and the lobar division must leave the bronchus intact without separating the superior segmental bronchus. It is possible to take the superior segment, if necessary, to achieve a complete resection and reimplant the basal segments on the main stem bronchus. The points of division of the bronchus should be perpendicular to the longitudinal axis of the airway and placed between cartilaginous rings. The margins are inked, and a frozen-section examination is performed. Once the margins are confirmed to be microscopically negative, the reconstruction is begun. We use an interrupted technique as described previously for the right upper lobe sleeve resection.

Because the left main stem bronchus is long, extensive proximal resections can be performed. This can create a technically challenging anastomosis because proximal exposure is obscured by the aortic arch. If required, the arch can be mobilized and carefully retracted to provide additional exposure. Even if a significant portion of proximal airway is removed, tension on the anastomosis is not a problem. The inferior pulmonary ligament should be released. Precise suture placement to account for
size discrepancy between the lobar bronchus and the main stem bronchus is particularly important.

**Left Lower Lobectomy Sleeve Resection ("Y" Sleeve)**

For lesions involving the left lower lobe orifice, with extension into the main stem bronchus but sparing the upper lobe orifice, a lower lobectomy with sleeve resection of the left upper lobe bronchus can be performed. The arterial and venous branches to the lower lobe are divided and the fissures are completed (Fig. 7.9). We dissect out and pass an umbilical tape around the left main stem and left upper lobe bronchus. Two silk stay sutures are placed in the main stem bronchus and used for retraction. The left upper lobe bronchus is divided at its origin. It is important for the division to be perpendicular to the long axis of the airway. Next, the main stem bronchus is divided proximal to the bifurcation and well proximal to the extent of the tumor. The specimen is removed from the field, and frozen-section examination of the airway margins is performed. Once the margins are confirmed to be microscopically negative, the reconstruction is completed.

The anastomosis is performed in an interrupted, as described previously for the right upper lobe sleeve resection, or in a running fashion. The lingular bronchus may arise quite proximally, and care must be taken when dividing the upper lobe bronchus to assure that the lingular bronchus remains intact. There is often a large size discrepancy between the upper lobe bronchus and the main stem. To account for the size discrepancy, precise placement of sutures is mandatory and is far preferable to taking a “tuck” in the main stem bronchus.

**POSTOPERATIVE CARE**

At the completion of a sleeve resection, the patient is extubated in the operating room. Postoperative pain relief is facilitated by a functioning thoracic epidural catheter. Pain control is re-evaluated periodically by the nursing staff and adjusted by the anesthesia pain service. The epidural catheter remains...
in place for the first 48 hours after operation in the majority of patients while in selected patients the epidural catheter remains in place until the chest tubes are removed. Atelectasis and subsequent pneumonia in the lung distal to the anastomosis must be avoided. This is accomplished by adequate pain relief and aggressive pulmonary toilet that may include frequent bronchoscopy if the patient is unable to clear their own secretions and consolidation occurs. We begin incentive spirometry as soon as the patient is awake and begin ambulation on postoperative day 1. The chest tube remains in place until there is no air leak, and the drainage is <200 ml/day. This usually occurs by postoperative day 3 to 5. The epidural catheter is capped 12 hours after the chest tube is removed, and oral narcotics are started. If adequate pain relief is obtained on an oral regimen, the epidural catheter is removed. Awake flexible bronchoscopy should be performed before discharge to assess the integrity of the anastomosis.

**OUTCOME**

The incidence of postoperative complications after sleeve lobectomy is 31.3% as reported by a recent meta-analysis. Major complications following sleeve resection include anastomotic dehiscence, empyema, and bronchovascular fistula. Fortunately, the incidence of these complications is low. We maintain a low threshold for bronchoscopy in the postoperative period. Persistent or evolving atelectasis in the lung distal to the bronchial anastomosis mandates bronchoscopy. A small partial anastomotic dehiscence (<30%) with a good pericardial fat wrap and no bronchopleural fistula can be treated conservatively, but consideration should be given to completion pneumonectomy based on the judgment of the surgeon. A complete dehiscence is caused either by anastomotic tension or more likely results from ischemia. This mandates reoperation and usually a completion pneumonectomy. An empyema can occur with or without a bronchopleural fistula. When it occurs without a bronchopleural fistula, it is handled with drainage, antibiotics, and ablation of any residual space with muscle transposition. Pleural space infection without a fistula is likely related to postoperative postobstructive pneumonia. When empyema occurs with a bronchopleural fistula from the anastomosis, a completion pneumonectomy is required, and management of the infected pneumonectomy space can be problematic.

Bronchovascular fistula presents with massive hemoptysis. This occurs when there is an anastomotic breakdown with peribronchial abscess formation, which necessitates into the adjacent PA. Under these circumstances, completion pneumonectomy is performed if this occurs in the hospital setting, which is unlikely because the time frame when this occurs usually approaches 3 weeks after operation. As expected, the mortality from this complication is very high.

The most frequent respiratory complication is pneumonia, which can be minimized by aggressive postoperative pulmonary toilet and adequate pain control. Local recurrence rates after bronchoplastic procedures are low (<5%) and similar to that achieved by pneumonectomy as long as the resection margins are free of disease. This further underscores the importance of frozen-section examination of the bronchial margins before completing the airway anastomosis. Late bronchial anastomotic strictures occasionally occur and are related either to ischemia or a healed partial anastomotic dehiscence. These usually can be managed with dilation and, if indicated, bronchial stent placement. The mortality rate for sleeve lobectomy is slightly higher than for routine lobectomy (3%) but significantly lower than for pneumonectomy (5.7%) (Tables 7.1).

*Stage I-II; *Stage I-IV.
Survival data reported in large series after sleeve lobectomy are comparable with those after standard lobectomy. Notably, the survival rates show better long-term survival and quality of life after sleeve lobectomy than pneumonectomy for similar lesions, suggesting that bronchoplastic resection, when technically feasible, is preferable to a pneumonectomy for the treatment of lung cancer, even in the presence of hilar and mediastinal lymph node metastases, in light of the improved pulmonary and cardiac functions, decreased morbidity and mortality, equal tumor clearance, local recurrence rate, and long-term survival.

ACKNOWLEDGMENT

The authors thank Doctor Elisabetta Grogioni for data management and editorial revision.

*Overall survival of PA and bronchial reconstruction. ns, not significant.
Dr. Rendina and coworkers have beautifully described the full spectrum of sleeve resections including those that are rarely performed. The point here is that sleeve resections can be performed on any lobe in the interest of parenchymal preservation. I agree completely with the authors that lung conservation should be the goal for any pulmonary resection as long as oncologic principles are not compromised. This makes it incumbent on the surgeon to not only have familiarity with bronchoplastic techniques but also with pulmonary artery reconstruction techniques. Important technical points to keep in mind are the absolute necessity for a clean bronchial cut perpendicular to the long axis of the bronchus for both the proximal and distal ends. Precise suture approximation making up the size discrepancy is also key because the distal bronchus almost always is significantly smaller than the proximal bronchus. Although tempting, we avoid taking a “tuck” in the larger bronchus and prefer instead to make up any discrepancy with suture bites spaced evenly around the entire circumference of the anastomosis. As opposed to the authors in most cases, I construct the anastomosis with a running technique using absorbable monofilament suture material usually of 4-0 size.

We also feel that it is important to wrap the anastomosis with a viable pedicle flap, and we prefer pericardial fat, which is attached to the bronchus. Aggressive postoperative pulmonary toilet is the key, and frequent therapeutic bronchoscopy may be required to clear secretions. Postoperative atelectasis in the reattached lobe should prompt early bronchoscopy to assure patency of the anastomosis as well as to clear any secretions. On the left side, the superior segment of the lower lobe may be taken as part of an upper lobe resection and the basal segments reimplanted on the left main stem bronchus. Depending on the size of the basal segmental orifice, there may be difficulties with secretion clearance as well as a fairly narrow lumen after the anastomosis. We routinely perform a bronchoscopy just prior to the patient’s discharge to assess the healing of the anastomosis and if there is any evidence of nonhealing, we err on the side of performing a completion pneumonectomy rather than wait to have major trouble with a bronchovascular fistula and its attendant high mortality.

The authors mention that anastomotic healing problems often stem from ischemia, but they do not comment on the role of mediastinal lymph node dissection in bronchial ischemia. It is possible, though unlikely, that a complete lymph node dissection that completely cleans the subcarinal space may contribute to bronchial anastomotic ischemia, and it is my preference to perform lymph node sampling especially in this area. I am not aware of any studies that definitively show that the bronchus can be devascularized by a lymph node dissection, but intuitively it makes sense especially with a thorough clean-out of the subcarinal space with its rich bronchial blood supply.

Bronchial sleeve resection may need to be combined with pulmonary artery resection and reconstruction especially on the left side. We do not hesitate to perform such a double-sleeve resection if that is what is required to save pulmonary parenchyma. It is our preference, and that of many others, to preferentially perform sleeve resection even when the patient’s underlying pulmonary function clearly indicates that the patient could tolerate pneumonectomy.

LRK
Sublobar pulmonary resections encompass all pulmonary resections of less than an anatomic lobectomy. They are subdivided into two distinct categories, anatomic, otherwise known as segmentectomy versus nonanatomic, commonly referred to as a wedge resection. Segmental resections were originally considered for patients with limited inflammatory disease, such as aspergilloma, tuberculosis, and bronchiectasis, but the indications have expanded to include metastatic disease to the lung as well as primary lung cancer in patients with poor pulmonary reserve.

It is easy to recommend sublobar resections for diagnostic procedures and benign disease but it is a more complicated decision when dealing with malignant disease. For disease that is metastatic to the lung where preservation of pulmonary parenchyma is a guiding principle, segmentectomy or wedge resection is the procedure of choice if surgery is indicated and the anatomy is amenable to sublobar resection. There is no clear evidence that more radical resection results in better survival or lower recurrence, and frequently these patients require resection of multiple lesions usually dictating smaller individual resections.

The decision to proceed with a sublobar resection for primary lung cancer is complex, and continues to evolve. The predominant indication is for patients with poor pulmonary reserve, yet this concept is ill-defined and inconsistently applied. Traditional teaching has mandated that patients require a predicted postoperative FEV₁ >0.8 to 1.0 L/s to have sufficient pulmonary reserve to maintain adequate short- and long-term functional capacity. However, two factors have contributed to thinking differently about the traditional teaching. Improvements in operative technique, anesthesia, postoperative pain management, and respiratory care have allowed successful thoracotomy and pulmonary resection even in patients with major comorbidity and/or with patients with a low preoperative FEV₁, even less than 0.5 L/s. Clearly these patients are at increased risk of postoperative pulmonary complications but it is unusual that these risks are prohibitive. These patients also have relative contraindications to radiation therapy or chemotherapy and may suffer similar or greater pulmonary complications or loss of function due to radiation when compared to surgery. In patients with major comorbidity a discrete intervention like a surgical procedure is often better tolerated than the less immediate, but insidious and progressive consequences of radiation.

The second factor changing the thinking regarding indications for surgery results from the recent experience with lung volume reduction surgery, which paradoxically often results in an increase in pulmonary function and exercise capacity when overinflated poorly functioning lung parenchyma is removed in selected emphysema patients. Patients with severe upper lobe-predominant emphysema, hyperinflation, and a tumor in the upper lobe, may actually be well served by a lobectomy or a lung reduction style of wedge resection, and actually have an improvement rather than a decrement in postoperative lung function.

The major factor that compels surgical consideration for lung cancer patients, even in those with major comorbidity, is that resection provides the only meaningful opportunity for cure. This is probably not an important factor if a patient’s anticipated life expectancy from his/her other disease(s) is less than 1 to 2 years, but for the majority of patients every effort should be made to try to offer surgical therapy with curative intent. Standard lobectomy should be possible in the majority of patients with nonpulmonary comorbidity.

The Lung Cancer Study Group in a classic study conducted a randomized trial that confirmed that lobectomy is the procedure of choice for patients with lung cancer, but sublobar resection and in particular segmentectomy are a reasonable compromise for those patients who are unable to tolerate a lobectomy. However, in the past few years several investigators have suggested that sublobar resections may have similar or equal outcomes to lobectomy in select patients. Lung cancer screening using low-dose spiral computed tomographic (CT) scanning has now been shown to reduce lung cancer deaths in high-risk patients (age >55 and smoking history >30 pack-years). As screening becomes more widely available, smaller lung cancers (<2 cm) are identified. It is likely that the incidence of sublobar resections of these early stage lung cancers is likely to increase. A number of thoracic surgeons already have challenged the standard dogma that lobectomy is mandatory for all lung cancer resections arguing that subcentimeter tumors may be adequately treated by wedge resection or segmentectomy, even in patients with adequate pulmonary reserve. More recently, several single-institution studies suggested that segmentectomy or extended wedge resections may be equivalent to lobectomy in appropriately selected stage IA lung cancer patients, but definitive evidence of oncologic equivalence awaits further follow-up. Currently, a National Cancer Institute-sponsored multicenter study (CALGB-140503) is underway comparing patient outcomes between lobectomy versus sublobar resections (wedge resection or segmentectomy) in small peripheral stage IA nonsmall-cell lung cancer. The study is powered such that results of this phase III randomized clinical trial will likely answer this important question.

Low-dose CT screening also has resulted in the identification of nodules with an alveolar filling appearance rather than a solid appearance, known as ground glass opacities (GGO). The appearance of GGOs on screening CT scans has led to a renewed appreciation of the subset of lung cancer known as bronchioloalveolar carcinoma (BAC), which in its pure form is a noninvasive subset of adenocarcinoma that has little potential for lymphatic and hematogenous metastases. Yet BAC may spread within the airway resulting in a late parenchymal metastasis appropriate for further surgical resection. GGO are frequently
BAC and may be best treated by sublobar resections since they have a low malignant potential by traditional criteria, yet may need additional pulmonary resections in the future due to the natural history of BAC. However, it is important to differentiate pure BAC from invasive adenocarcinoma with BAC features. The former may be treated by sublobar resection, but the presence of invasive carcinoma should indicate the need for a lobectomy if possible.

There are anatomic considerations that influence appropriateness of sublobar resections as well. Although exceptions always exist, generally segmentectomy and wedge resection are reserved for those patients with more peripheral and smaller tumors, a rough guideline being in the outer third of the lung parenchyma, and less than 3 cm in diameter, respectively. It is possible to consider limited resection for larger or more central tumors, but these will almost always require an anatomic segmentectomy in order to achieve adequate tumor margins. Another anatomic factor is the location of the tumor within the lung. A tumor that is close to or crosses an anatomic segment may require a bisegmentectomy or “cheating” into the adjacent segment with a staple line beyond the segmental boundary. Wedge resections are easiest (i.e., most successful) near acute lung edges, where it is possible to achieve adequate deep margins without encountering lung parenchyma that is too thick to staple. Therefore, peripheral tumors at the lung apex, lung base, or adjacent to a fissure are most amenable to an effective wedge resection.

Segmental resections are based on the principle of following the lymphatic drainage and bronchial branches of the segments resected. This provides a theoretical advantage over nonanatomic wedge resection in the treatment of primary lung cancer. However, segmental resections are also the least common type of pulmonary resection performed and are technically more challenging than lobectomy or pneumonectomy. This frequently results in wedge resections being performed as a default sublobar resection when parenchymal preservation is desired, due to inexperience with the indications for segmentectomy and lack of confidence in the technical components of segmentectomy.

Wedge resection of the lung is performed for a wide variety of indications, including lung biopsy for interstitial or infiltrative processes, excisional biopsy of a lung nodule, and definitive resection of a primary lung cancer or metastatic disease. With the current variety of standard and endoscopic staplers, wedge resection has become extremely easy and reliable. But, as a result, wedge resection is at risk of being overutilized, the technical simplicity being a seductive attraction to the surgeon with little thoracic surgical training or experience. Most of these surgeons have little or no experience with segmentectomy and so frequently will prefer a wedge resection procedure when a segmentectomy, or even a lobectomy, would be preferred for anatomic or oncologic reasons.

There are clear theoretical reasons explaining why anatomic segmentectomy may be superior to wedge resection for primary lung cancer. A segmental resection results in more reproducible deep parenchymal margins, since it extends the resection to the pulmonary hilum. Segmentectomy also incorporates the lymphatic drainage and interlobar lymph nodes and so may result in both more thorough resection as well as more accurate staging. Several studies have suggested decreased rates of local recurrence with segmentectomy, but no well-designed study comparing segmentectomy to wedge resection has been performed. However, it is quite possible that the appearance of better cancer outcomes after segmentectomy may be substantially biased because of inappropriate or inadequate wedge resections being performed by less-experienced surgeons. It is reasonable to postulate that outcomes between wedge resection and segmentectomy for primary lung cancer may be similar as long as three principles are adhered to: (1) adequate sampling of N1 and N2 lymph nodes to exclude stage II and stage III disease; (2) at least a 2-cm parenchymal margin around the tumor; (3) restriction of lung cancer surgery to surgeons trained in thoracic surgical oncology who perform a high volume of pulmonary resections in order to have the experience and expertise to select patients who truly require sublobar resection, or who may benefit from segmentectomy rather than wedge resection.

Since sublobar resections are contraindicated in patients with nodal involvement, careful preoperative and intraoperative lymph node staging should be performed. Positron emission tomography (PET) adds significant accuracy to the staging accomplished with chest CT, but still suffers from false-positive and false-negative studies. Mediastinoscopy is indicated to confirm or exclude N2/3 nodal disease in cases of a positive PET scan. Our practice is to perform mediastinoscopy on every lung cancer patient during the same anesthetic as the planned pulmonary resection in order to detect all possible stage III patients prior to thoracotomy, but many would consider this optional for peripheral T1 N0 M0 tumors with a normal CT and PET in the hilum and mediastinum.

At the time of thoracotomy, representative N1 and N2 lymph nodes should be sampled since stage II/III patients require lobectomy at a minimum in order to have the confidence of a complete resection.

**Segmentectomy**

Intimate knowledge of pulmonary anatomy, and its variants, is crucial in order to perform pulmonary segmentectomy. A complete bronchoscopic examination must be performed at the time of operation. Identification of abnormal segmental anatomy will aid in the planning of the surgical procedure; extrinsic segmental compression or presence of endobronchial tumor in the segmental orifice is a contraindication to segmental resection. Those segments that are amenable to segmentectomy include the apical, anterior, and lingular segments of the right upper lobe and the superior segment and medial basal segment of the right lower lobe. The middle lobe is rarely considered for segmentectomy since there is little gained from a sublobar resection with this small lobe. The left lung segments amenable to segmentectomy are the apico-posterior, anterior, and lingular segments of the left upper lobe, and the superior and anteromedial basal segments of the left lower lobe. The basal segments may be resected as a unit on either side, sparing the respective superior segment that can provide significant pulmonary function and help to fill the space of the lower hemithorax.

The initial steps of the procedure involve assessment of the tumor size and location to determine the technical feasibility of segmentectomy, as well as determining any evidence of pleural, mediastinal, or nodal involvement that precludes curative sublobar resection. The anterior and apical segmental arterial branches are dissected at the medial and superior aspect of the pulmonary hilum, while the posterior, superior, and basilar segment arteries are found in the fissure (Fig. 8.1). After clearly identifying the appropriate segmental vessel it is divided using standard technique. Dissection of the superior pulmonary vein from the hilum and extending into the lung parenchyma allows identification and division of the respective vein draining the upper lobe segments, although some surgeons prefer to divide the posterior segmental vein within the fissure. The separate superior segment vein...
Fig. 8.1. (A) With the fissure open, the pulmonary arterial branch to the superior segment is dissected out. Note the tumor at the apex of the right lower lobe. (B) The superior segmental branch of the pulmonary artery has been ligated, and the superior segmental bronchus is dissected out. (C) The lung is retracted medially, and the superior segmental branch of the inferior pulmonary vein is dissected out. (D) The intersegmental plane is opened and the specimen is removed. Individual bronchioles and vessels can be ligated or cauterized.
and basilar segment confluence is readily identified after division of the pulmonary ligament and dissection of the inferior pulmonary vein, but identification of the medial basilar and anteromedial basilar vein is more difficult and requires following the basilar branches into the lung parenchyma. The posterior aspect of the fissure should be completed for posterior, apico-posterior, and superior segmentectomies and the anterior fissure completed for the anterior, lingular, and basilar segments. No fissure division is necessary for the right apical segment. Lymph nodes encountered during vascular control and bronchial division should be resected and submitted for pathologic examination to refine intraoperative tumor staging.

The segmental bronchus is identified deep to the divided pulmonary artery. Peribronchial lymph nodes are resected separately or taken with the specimen to be resected, as part of encircling the airway and confirming that it is the appropriate bronchus leading to the segment to be resected. The bronchus can be divided at its origin with a knife and oversewn with fine absorbable sutures, or alternatively can be divided using a stapler and the stump closed with reinforcing sutures.

The historic method of parenchymal division was accomplished by simultaneous traction on the divided segmental bronchus along with finger fracture blunt dissection along the intersegmental plane defined by the venous anatomy. This technique has the advantage of avoiding restriction of the adjacent segment by a staple line, as well as clear development of adequate margins, but it is tedious to oversew and cauterize the bleeding and air leak sites on the surface of the raw lung parenchyma, and prolonged air leak is a more common postoperative complication. Therefore, stapled division of the pulmonary parenchyma is almost universally employed because surgeons are more comfortable with the technique as opposed to finger fracture and it minimizes the problems of postoperative air leak. To do this correctly, the surgeon must know the parenchymal extent of the segment very well. If there is any uncertainty, a few moments with a surgical atlas is a useful refresher. However, with the stapler it is perfectly acceptable to take a portion of the adjacent segment if this will allow a more complete resection of the tumor with a 2 cm margin. Retracting the nodule with one hand, fingers deep to the nodule on the underlying normal parenchyma, while the other hand applies and fires the stapler can help to assure and maximize an adequate margin during stapling. The surgeon has to approximate the true margin which is different in atelectatic versus inflated parenchyma, and recognize that approximately 1 cm is removed by the pathologist (the staple line) before assessing the histologic margin.

### WEDGE RESECTION

The most common technique of nonanatomic pulmonary wedge resection utilizes the linear stapler. Stapling is readily available and effectively seals the lung parenchyma to minimize air leak. As mentioned above, a stapled wedge resection is most amenable to lesions in the outer third of the lung parenchyma and adjacent to an acute edge of lung at the fissure, apex, or base. These are rough guidelines however, and deeper lesions can often be successfully wedge excised, even if they do not fit the routine criteria for wedge resection. But if a deep wedge resection removes a majority of the lobe, or compromises the remaining lung parenchyma, the indications for sublobar resection should be reexamined and reconsideration given to formal lobectomy.

Although stapling is deceptively simple there are several important principles that should be followed to maximize success. First, margins are assured and maximized by the same strategy as outlined in the segmentectomy section—manually lifting the nodule away from the underlying lung while applying and firing the stapler (Fig. 8.2). Second, one must carefully judge the thickness and pliability of the lung parenchyma to be stapled. Most areas of normal lung can be successfully incorporated and sealed with a 3.5 mm or 4.8 mm staple line, but some deep areas may be thicker and not appropriate for stapling. Other patients may have underlying interstitial lung disease or inflammation that results in thickened parenchyma. Attempts to force a stapled wedge resection in these cases may result in staple line dehiscence with serious bleeding and bronchial air leak. There are no gauges to guide the thickness of lung that can be successfully stapled; so this requires surgical experience and judgment. If dehiscence does occur it should be repaired with a running absorbable monofilament suture, incorporating the faulty staple line, the edge of visceral pleura, and the raw lung parenchyma. We prefer a two-layer suture with a running horizontal mattress followed by a simple running suture.

The other major technique of wedge resection is cautery or laser excision, sometimes referred to as a “precision” resection or a Perelman procedure. This technique is excellent for a benign lesion, such as a hamartoma, particularly when the nodule is deeper and not present at a lung surface. In these cases the nodule can be essentially enucleated from the surrounding lung parenchyma with very minimal loss of normal lung tissue. The second indication for cautery excision is a metastatic nodule in the lung that is deeper in the lung parenchyma or near the pulmonary hilum. The technique of cautery excision may allow successful removal of the nodule with 1 to 2 cm of parenchymal margin with anatomy that would have otherwise required a lobectomy. The third indication is a nodule surrounded by thick or stiff lung that does not have the compliance to accept the compression of a staple line. Cautery resection is rarely performed for primary lung cancer, however, since the margins are less than would normally be desired.

The technique of cautery excision is similar for the electrocautery and the Nd:YAG laser (Fig. 8.3). The desired boundary of the resection is marked on the visceral pleura with the lung partially inflated, and then progressively deepened circumferentially around the nodule with frequent examination of the margin. The excision is performed slowly to allow effective cauterization of the underlying parenchyma. When the resection is complete, the raw lung parenchyma can be oversewn with a running two-layer closure as outlined above, but the surface can also be left as a raw surface if it is superficial and hemostatic with a minimal air leak.

Video-assisted thoracic surgery (VATS), also known as thoracoscopy, can frequently be employed in wedge resections, combining a minimally invasive approach to minimize recovery and morbidity. Much of the ability to palpate the lung is lost with VATS, however, making identification of the nodule more difficult, and precluding a systematic bimanual

![Fig. 8.2. A wedge of lung is resected using a linear stapler.](image-url)
palpation of the lung for other pathology. In these cases it is extremely important for the surgeon to have an ability to accurately interpret the two-dimensional CT images into a three-dimensional anatomic location to achieve a high yield of nodule identification. Then if one of the thoracoscopic ports can be placed near the nodule it is possible to palpate the lung digitally through the port to help in localization. This technique is successful in nearly all cases of peripheral lung nodules. An alternative localizing strategy is for preoperative radiologic placement of a wire guide, but this adds to the time and complexity of the surgical procedure and should not be necessary with careful planning and minimally invasive palpation. VATS wedge resection does have a limitation of the technique, however. It is much more difficult to achieve the same degree of nodule retraction with direct tactile feedback and so deep margins may be less reliable. On

the other hand, this inability to hold the nodule can often result in the opposite effect, with overly large wedge resections performed to offset any uncertainty in the adequacy of the margin.

VATS is performed routinely for wedge resections, and is now also increasingly performed for standard lobectomy. However, the technical demands of a segmentectomy are still an indication for a thoracotomy at most thoracic surgery centers.

CONCLUSION

Sublobar pulmonary resections are an attractive option for benign or metastatic lung nodules, but wedge resection or segmentectomy may also be indicated in patients with primary lung cancer with poor pulmonary reserve, subcentimeter cancers, or small focal BAC. Few surgeons are familiar with the technique of anatomic pulmonary segmentectomy. This is unfortunate since segmentectomy provides a useful option for patients with poor pulmonary function and anatomy unfavorable to a wedge resection, or those with primary lung cancer where there is a desire to preserve pulmonary parenchyma. Patients undergoing sublobar resections should be carefully staged preoperatively and intraoperatively to exclude more advanced disease that is not appropriate for limited resection. Lobectomy is still the procedure of choice for nonsmall-cell lung cancer, but sublobar resections are reasonable compromise resections that are superior to the alternatives of radiation and chemotherapy.

SUGGESTED READINGS

Fig. 8.3. A deep-seated nodule is delivered up into the field, and a cone of lung is resected using precision electrocautery.
Parenchymal conservation should always be considered when approaching any lung resection. That said, the definitive resection for primary lung cancer remains lobectomy with mediastinal lymph node dissection. As the authors correctly point out, certain tumors are amenable to anatomic segmental resection with the expectation that oncologic outcome is equivalent to lobectomy. However, anatomic segmental resection should not be compared to or substituted with a nonanatomic wedge excision, a procedure that is associated with a significantly increased incidence of local recurrence and inferior survival. Wedge excision for primary lung cancer results in a compromised parenchymal margin and a complete lack of segmental lymph node staging information. Conversely, anatomic segmentectomy produces an adequate parenchymal margin and, because the segmental bronchus is taken, results in excision of the peribronchial segmental lymph nodes and thus complete staging when accompanied by mediastinal lymph node dissection.

Lingular sparing upper lobectomy on the left and superior segmentectomy on either the right or the left are the easiest segmental resections, whereas segmental resections of the right upper lobe can be quite difficult depending on the location of the lesion. When resecting the basal segments and leaving the superior segment of the lower lobe, it is important to leave the superior segment attached with the upper lobe to prevent torsion. The segmental artery is the key to segmental resection. Once the segmental artery is identified and divided the segmental bronchus becomes apparent. The segmental vein is usually taken following division of the bronchus. Once the bronchus and vessels are taken the line of parenchymal division becomes obvious. It should be underscored that segmental resection is more difficult than lobectomy because of the necessity of following the vessels and the bronchus into the parenchyma. In experienced hands segmental resection may be done using VATS techniques just as lobectomy may be done. With the advent of CT screening in individuals at high risk of developing lung cancer and the ability to recognize very small, early lung cancers it is important that thoracic surgeons be familiar with the techniques of anatomic segmentectomy. This is especially critical for those lesions formerly referred to as bronchioloalveolar carcinomas that have been reclassified as either adenocarcinomas in situ or minimally invasive adenocarcinoma with lepidic growth pattern as these patients may develop additional lesions that are best treated by resection.
The surgical management of both benign and malignant tracheal conditions is challenging, often daunting, but very rewarding because of the impact it can have on the daily life of the patient. Technical challenges are posed by both the resection and the reconstruction of the involved airway. The entire process is a logistic as much as a technical exercise, best conducted by an experienced team including radiologists, pulmonologists, thoracic surgeons, otorhinolaryngologists, thoracic anesthesiologists, skilled nurses, and respiratory therapists. The timing and the extent of resection are dictated as much by the presence or absence of comorbidities, as by the nature, location, and extent of the resection required. In carefully selected and well-prepared patients, tracheal resection and reconstruction offer a definitive treatment with excellent long-term outcomes.

Broadly speaking, there are three different types of tracheal resections, each requiring a specific operative approach and surgical technique depending on the location and extent of tracheal involvement. The most straightforward of these is a segmental resection of the trachea with end-to-end anastomosis. Resections at either end of the trachea, specifically a laryngotracheal resection at the proximal end, or a carinal resection at the distal end, may require more complicated anastomotic reconstruction and complementary release maneuvers to reduce tension.

**SURGICAL ANATOMY OF THE TRACHEA**

The trachea is a more or less “D”-shaped tube which, in the adult, is of fairly uniform caliber connecting the larynx above with the main bronchi below. It is supported by c-shaped cartilaginous rings and a nonsupported posterior membranous wall. The elastic properties of the cartilaginous portion provide for some degree of lengthening, such as when the head is extended, and the mobile, nonreinforced posterior membranous wall allows a certain degree of change in caliber in response to changes in pleural pressure. The trachea begins in the neck as an anterior cervical structure and terminates distally as a posterior mediastinal structure. Its blood supply is primarily a segmental one with branches from the inferior thyroid artery, the internal thoracic artery, and the bronchial arteries along with variable contributions from the subclavian and brachiocephalic arteries. The blood supply enters the trachea along either lateral aspect from which the vessels travel horizontally between cartilaginous rings. Because the blood supply to the trachea comes primarily from multiple lateral end vessels, it is essential not to circumferentially devascularize the trachea for more than 1 to 2 cm. However, complete blunt anterior and posterior dissection is well tolerated for purposes of mobilization without consequent ischemia to the trachea.

Along its entire posterior aspect, the membranous wall of the trachea is adjacent to the esophagus. Along the anterior surface of the trachea, the thyroid lies at the level of the cricoid and first tracheal ring. The left brachiocephalic artery crosses anteriorly at a variable position, which may be as high as 1 to 2 cm above the sternal notch, or a similar distance inferior to the sternal notch. The right azygos vein lies adjacent to the right lateral aspect of the distal trachea at or just above the tracheobronchial angle. The aortic arch lies in the left anterolateral position to the distal trachea, and the pericardium lies immediately anterior to the carina. The left recurrent laryngeal nerve lies in the tracheoesophageal groove throughout the length of the trachea, while the right recurrent laryngeal nerve occupies a similar position on the right side from the level of the right subclavian artery proximally. Both nerves ascend to the larynx posterior to the cricoid lamina. All of these anatomic relationships have significant implications for the approach and technique used for mobilization and resection of the trachea. In addition, in older patients with increasing kyphosis, a loss of tracheal elasticity and possible calcification may all have significant implications for the approach and extent of safe tracheal resection.

**ETIOLOGY OF POTENTIALLY RESECTABLE TRACHEAL LESIONS**

Indications for tracheal resection and reconstruction include both benign and malignant conditions with benign conditions far outweighing the malignant ones. The most common indication is postintubation injury to the airway followed by inflammatory conditions especially idiopathic subglottic stenosis, which occurs primarily in young women. Currently, tracheal resection for Wegener’s granulomatosis, relapsing polychondritis, amyloidosis, and other inflammatory conditions is exceedingly rare.

Postintubation tracheal stenosis remains the most frequent indication for tracheal resection, though the spectrum of postintubation injuries has shifted in recent years. Formerly, postintubation stenosis at the cuff site of endotracheal tubes or tracheostomy tubes was the most common source of injury followed by stomal stenosis due to loss of the supporting cartilaginous arch at the tracheostomy stoma site. In recent years, however, postintubation stenosis at or just below the cricoid cartilage has become more common and represents a more complex problem. These injuries are usually caused by high placement of a tracheostomy tube with subsequent damage and infection at the level of the cricoid cartilage often extending proximally to within 1 cm of the vocal cords. This injury may be associated with total obliteration of the airway in the subglottic region leaving the patient dependent on a tracheostomy tube and unable to speak (Fig. 9.1). The reason for this increasing number of high airway strictures is uncertain, but the use of percutaneous tracheostomies with malpositioning of the tracheostomy site, urgent posttraumatic placement of a tracheostomy tube in patients who are now more likely to survive complex trauma.
Section I: General Thoracic Surgery

A B

Fig. 9.1. (A) Typical circumferential tracheal stenosis at the site of endotracheal tube cuff. The circumferential scarring and progressive airway narrowing typically presents as increasing stridor 6-8 weeks following extubation. (B) Typical stomal stenosis, distal to the cricoid seen at the level of the second tracheal ring due to loss of the anterior support of one or more tracheal rings. The side walls have collapsed. Such lesions may present years after the tracheostomy when aging, or co-morbidities, accentuate the limitations associated with airway narrowing. The anterior-posterior diameter is usually normal as seen here.

and the rising incidence of morbid obesity making even elective tracheostomy more difficult to site at a desirable position at the second or third tracheal ring all may contribute.

Among malignant conditions requiring tracheal resections, adenoid cystic carcinoma remains the most common. Resection for primary squamous cell carcinoma of the trachea is uncommon both because of the rarity of the condition and the commonly advanced stage of the tumor at the time of diagnosis in addition to improved results with radiotherapy as an alternate option. Tracheal resection for secondary involvement of the airway with malignant tumors arising in other sites is limited almost exclusively to resection associated with direct invasion by thyroid carcinoma.

Whatever the indication, appropriate selection of patients and judicious selection of timing of resection are essential in producing a satisfactory result. Evaluation of both the location of the lesion as well as the extent of the resection required is critical in making a decision as to whether resection is the optimal treatment and if so the type of resection required. In addition, some thought also must be given to the use of temporizing maneuvers to delay resection until the patient is in an ideal condition. The use of silicone stents such as T-tubes frequently aides in preoperative management, and the use of permanent stents as an alternative to resection may, in some cases, prove to be a reasonable strategy.

CLINICAL PRESENTATION AND DIAGNOSTIC STUDIES

The presenting symptoms of patients with tracheal obstruction vary greatly depending on the etiology of the airway compromise. Postintubation stenosis usually presents relatively early following the hospital course, which necessitated ventilator assistance in the first place. If the tracheal damage is proximal usually caused either by a traumatic intubation or injury to the cricotracheal junction from an endotracheal tube or a highly placed tracheostomy stoma, airway obstruction may first be recognized by the inability to decannulate the patient because of an inadequate upper airway. More often postintubation cuff stenosis generally presents as increasing shortness of breath with onset 4 to 8 weeks after decannulation when the full thickness damage to the trachea from the resulting inflammation and fibrosis leads to circumferential scarring and contraction (Fig. 9.2A). An exception is stomal stenosis whereby loss of the anterior supporting portion of the trachea, either due to too large a tracheostomy stoma or extension of the stoma by leverage on the tracheostomy tube by unsupported connection between the ventilator tubing and the tracheostomy, results in collapse of the lateral walls. This so-called inverted V or A-frame stenosis may first present years or even decades after the tracheostomy tube was removed (Fig. 9.2B).

Thyroid carcinoma invading the trachea may be suspected either because of stridor suggesting airway compromise or, for lesser invasion, discovered at

Fig. 9.2. (A) Benign cartilaginous tumor (tracheopathia osteochondroplastica) in the proximal trachea of a 20-year old male with a 10 year history of asthma-like symptoms. (B) Flow Volume Curve showing significant inspiratory airflow limitation with relatively well-preserved expiratory flow. The dots outline the predicted, normal curve.
the time of thyroidectomy. If there is any question ideally, a bronchoscopy should be performed prior to undertaking the thyroidectomy. Squamous cell carcinomas of the trachea may present with hemoptysis or with a gradual increase in breathlessness or stridor especially with exertion. Adenoid cystic carcinomas that are usually quite slow growing may present with a history of several years of gradually increasing dyspnea on exertion ultimately resulting in shortness of breath with routine activities. A history of increasing breathlessness with stridor going back five years or more is not uncommon.

Furthermore, the degree of airflow obstruction is influenced by the location as well as the physical size of the tumor. This is illustrated in Figure 9.3A and 9.3B.

Benign tumors of the trachea may also present with a very long history of gradually increasing exertional dyspnea. Often these patients have had an extensive work-up for asthma-like symptoms. These tumors, which ultimately may fill the tracheal lumen, often are attached at a very small base or stalk, leaving the rest of the tracheal wall uninvolved. Because of the ability of the intrathoracic trachea to expand on inspiration during normal respiration, such patients may not be noticeably short of breath but may be found to have an FEV₁ of <10% of predicted because forced expiration compresses the trachea against the tumor causing the near total obstruction.

The diagnosis of postintubation stenosis is usually apparent from the history and confirmed by bronchoscopic evaluation. The diagnosis of both benign and malignant tumors is also usually obvious on the basis of radiographic and bronchoscopic assessment. Conversely, the diagnosis of idiopathic subglottic stenosis is usually made based upon the typical presentation in females, with gradual progression of stenosis and the exclusion of other benign conditions such as previous intubation, Wegener’s granulomatosis and relapsing polychondritis (Fig. 9.4). The diagnosis is subsequently confirmed with bronchoscopy.

**ASSESSMENT OF THE EXTENT OF AIRWAY INVOLVEMENT AND RESECTABILITY**

Routine preoperative assessment includes a carefully obtained history, physical examination, bronchoscopic evaluation, and pulmonary function studies in addition to imaging. For patients who do not have a tracheostomy tube in place, computed tomography (CT) imaging usually precedes bronchoscopic evaluation. For patients with a tracheostomy in place, the reverse is true and at the time of CT imaging the best study is obtained if the tracheostomy tube can be temporarily removed. This involves determining in advance whether or not the patient can maintain a satisfactory airway for 30 to 60 seconds without the tracheostomy tube in place. If so, the CT scan is done with a physician in attendance. Once the patient is positioned for the scan, the tracheostomy tube is removed and immediately reinserted after the scan is completed. It is best to practice this maneuver with the patient before proceeding with the actual scan. When possible the CT scan should be done with the acquisition of images in both inspiration and expiration. Evaluation of the CT images is best done with a three-dimensional reconstruction along with the assessment of both the axial and sagittal slices.

Depending on the exact software used for the CT analysis a three-dimensional reconstruction usually defines quite nicely the location and the extent of the narrowing of the airway column. However, it does not demonstrate the actual wall thickness or consistency and it is for this reason that the evaluation of the axial sections in particular is essential. It is not uncommon for the airway wall above and below the narrowed segment to be extensively involved with calcification and scarring. In such a situation, the extent of resection will be determined not only by the length of narrowed airway but also by
the amount of tracheal wall involvement proximal and distal to it, which may have considerable influence on the ability to reconstruct the airway if one resects back to normal airway at either end. Based upon the radiologic and endoscopic assessment, a decision can be made as to the resectability as well as choice of operative approach, and the likelihood of release maneuvers that may be required in order to assure a satisfactory, relatively tension-free primary anastomosis (Fig. 9.5). The circumstances most likely to produce scarring, thickening, and calcification include trauma to the neck region, one or more previous tracheotomies, inhalation injury, or the presence of a postintubation tracheoesophageal fistula. Scarring of the airway wall beyond the segment of actual stenosis may provide significant technical difficulty at the time of resection. This is due to the loss of mobility of the airway and loss of tracheal elasticity, which ordinarily help to reduce tension on the anastomosis. Calcification makes it difficult to place sutures through the wall, and mediastinal scarring leads to fixation of the airway and difficulty in mobilization to help bring the severed margins of the resected airway together. Previous sternotomy, obesity, and kyphosis also influence resectability, the surgical approach, and the likelihood of a favorable outcome.

**BRONCHOSCOPIC ASSESSMENT**

Bronchoscopic evaluation by the surgeon is an essential step in determining the management and resectability of a tracheal or laryngotracheal lesion. This assessment is usually done beginning with flexible bronchoscopy following nasopharyngeal topical anesthesia with the patient mildly sedated so as to be able to assess vocal cord function. Following this, the flexible bronchoscope is advanced through the larynx. If the patient does not have critical airway stenosis, the level of sedation can be increased after assessment of the vocal cords and flexible bronchoscopic assessment continued with or without the use of a laryngeal mask to help support ventilation. Should preoperative or initial bronchoscopic visualization suggest the presence of a markedly narrowed airway in the absence of tracheostomy tube in place, a decision must be made whether or not to traverse the narrowed segment with the flexible bronchoscope out of concern for causing edema or bleeding, which could lead to a critical situation. In this circumstance, the presence of a skilled thoracic anesthesiologist, a skilled nursing team, and a wide variety of equipment appropriate for the situation is essential. This includes rigid bronchoscopes in sizes ranging from 5 mm upward, flexible bronchoscopes ranging from pediatric to therapeutic in size, appropriate-sized dilating balloons, and equipment for jet ventilation through the open, rigid bronchoscopes. It is important to avoid muscle relaxants until a safe airway has been established. This may be greatly facilitated by the use of a laryngeal mask and the use of Dexmedetomidine (Precedex) sedation, which is relatively unique in its ability to provide sedation without causing respiratory depression. Its use is ideal in the patient requiring awake, rigid bronchoscopic dilatation of the critically narrowed airway.

Until recently, the author favored initiating dilatation of a critical airway stenosis with a No. 5 rigid pediatric bronchoscope converting to general anesthesia once the initial passage of the bronchoscope beyond the stricture had been accomplished. Increasingly, however, the use of a dilating balloon through the therapeutic bronchoscope, which itself is passed through a laryngeal mask, has proven very satisfactory and is somewhat less demanding of the skills and experience of the thoracic surgeon and anesthesiologist. The one concern with initiating dilatation with a balloon rather than with a rigid bronchoscope has been that any bleeding or edema might convert the critical airway to an obstructed airway necessitating an emergent tracheostomy. With the use of a dilating balloon having a diameter in the 6 to 8 mm range, this has

---

*Fig. 9.5. CT Airway study on a 50-year old woman with a post-tracheostomy stricture presenting with increasing stridor 5 weeks post-extubation. (A) The extensive narrowing of the air column includes both the stomal site and cuff site. (B) Axial view showing thickness and calcification in airway wall requiring extensive resection to achieve satisfactory margins for anastomosis.*
not been a problem and provides increased safety of the airway for the subsequent dilatation maneuvers. Generally, this would set the scene for converting to a general anesthesia including, if necessary, the use of paralytic agents, for further dilatation using rigid bronchoscopic techniques. The use of progressively larger rigid bronchoscopes undoubtedly provides a better dilatation than the use of progressively larger dilating balloons even if their inflated diameter is equal to or greater than that of the rigid bronchoscopes selected for dilatation (Fig. 9.6).

After the narrowed segment of trachea has been dilated, the airway should be reassessed with the flexible bronchoscope to determine the stability of the airway. Ideally, the dilatation procedure should lead to a more secure upper airway, eliminating the need for urgent tracheostomy or surgical intervention while further assessment of both the airway and the patient’s suitability for resection is considered.

**TIMING OF SURGICAL INTERVENTION**

The appropriate timing of a tracheal resection is one of the most important factors in producing a satisfactory outcome. This is especially true for benign lesions as many temporizing maneuvers can be used to delay surgical resection until the patient’s condition is optimal. These temporizing procedures may include repeated dilatation, use of a silicone T-tube stent, or even prolonged use of a tracheostomy tube to provide a safe airway.

As previously noted, most tracheal resections are currently done for postintubation strictures or malacia of the airway. In many cases, the airway compromise is recognized initially within a couple of months of the initial intubation, when the patient has not completely recovered from the condition (trauma, cardiac surgery, acute respiratory failure, etc.), which necessitated intubation in the first place. In such patients, it is advisable to temporize until the patient is fully active and has achieved their maximum possible overall recovery. This often means delaying definitive resection for a year or more. Any patient with potentially reversible medical conditions should have resection deferred until such time as they are deemed best equipped from a cardiopulmonary standpoint, have attained the best possible physical conditioning, and any ongoing steroid requirements for persistent underlying lung disease have been reduced or eliminated. The need for postoperative ventilatory assistance following a tracheal resection should be assiduously avoided as it is usually associated with an unsatisfactory result. Reoperation after a failed tracheal resection is clearly associated with increased risk, complexity, and an inferior result compared with an initial, successful reconstruction.

Most cases of critical stenosis can be managed for 7 to 10 days with a single dilatation using rigid bronchoscopy, after which a plan for long-term management should be formulated. If internal tracheal stents are to be used, only silicone stents or T-tubes should be utilized since expandable metal stents may cause further mucosal damage and complicate the subsequent surgical resection. If a silicone T-tube is employed, it should be used only if the patient can breathe comfortably with the horizontal (external) limb capped except for instillation of saline and mucolytic agents. If the patient is unable to breathe comfortably with the horizontal limb capped, then the upper, vertical limb will become clogged with mucus and it is preferable that a tracheostomy tube rather than a T-tube be utilized. If the patient presents with upper airway obstruction and no tracheostomy stoma is present, the stoma for a temporizing tracheotomy tube, or T-tube should be made through the damaged portion of the airway if at all possible. This will avoid damaging an additional segment of the trachea, which further complicates a subsequent resection and reconstruction.

If airway compromise, whether from a benign or malignant condition, is the patient’s primary problem and the patient is otherwise suitable for resection, it still maybe advisable to improve the airway, whether by dilatation of the stricture or by endoscopic partial resection of an obstructing tumor to allow the patient to improve their exercise tolerance and improve secretional clearance to further minimize the likelihood of a postoperative pulmonary infection. Usually 3 to 4 weeks of such preparation suffices. If the patient presents with a tracheostomy tube in place, then the use of a silicone T-tube placed through the tracheostomy tube is stent the narrowed segment of airway is often the optimum method of temporizing and can be in place for an indefinite period. In some situations, leaving a T-tube in place for 6 to 9 months before its removal may lead to a stable widely patent airway, thus eliminating the need for a resection. In the majority of such cases, however, temporary stenting alone is not sufficient and a resection is usually required (Fig. 9.7).

**PRINCIPLES OF TRACHEAL RESECTION**

As previously noted, tracheal resections can, in general, be divided into three anatomic categories: those requiring a segmental trachea resection with end-to-end to tracheal anastomosis; those involving a resection of the upper trachea and cricoid region with a resulting laryngotraheal anastomosis; those with resection of the distal trachea including the carina with anastomosis between the distal trachea and one or both main bronchi. This latter resection is usually indicated for malignant tumors and is dealt with in Chapter 10.

For all surgical resections and reconstructions of tracheal lesions, the principles are the same. The limits of tracheal resection must extend to healthy, normal airway, whenever possible. Compromise of this principle increases the possibility of an unsatisfactory outcome with persistent or recurrent stenosis. Circumferential dissection of the trachea more than a centimeter or so beyond the resected ends should be avoided so as not to jeopardize the tracheal blood supply. However, blunt dissection for considerable distance along the anterior wall of the trachea, and posteriorly between the membranous wall of the trachea and
the esophagus usually is not a problem. Finally, undue tension on the anastomosis should be avoided with and tension-relieving maneuvers employed when necessary. These include the customary postoperative maintenance of partial flexion of the head with a tethering suture between the under surface of the chin and the skin anterior to the manubrium, a suprathyroid release of the larynx, and the right hilar intrapericardial release, particularly useful for distal tracheal and carinal resections. With all of these maneuvers, up to one-half of the trachea may be resected in some cases, usually in younger patients, without preexisting scarring from a tracheostomy, and with good flexibility of the head and normal tracheal elasticity.

One of the more serious complications that can be incurred during tracheal resection involves injury to the recurrent laryngeal nerves. For benign conditions, keeping the dissection on the cartilaginous tracheal wall will prevent injury to the recurrent laryngeal nerves without the necessity of actually identifying them or dissecting them out.

ANESTHETIC EQUIPMENT FOR TRACHEAL RESECTION

The management of the airway during tracheal resection and reconstruction requires constant communication between the surgeon and an experienced anesthesiologist. The available equipment should include a laryngeal mask, a series of endotracheal tubes ranging from size 5 upwards; a high-frequency jet ventilator set at 15 to 20 lbs per square inch of pressure at a rate of 100 to 120 cycles per minute; appropriate jet catheters 1½ to 2 times the length of the endotracheal tube, with the distal side holes cutoff; a set of sterile anesthetic tubing to be passed from the operative field to the anesthesia machine for ventilation across the surgical field; a sterile flexible armored endotracheal tube, size 6 or 7 to be used when intubating the distal, severed, airway across the operative field; and Parker endotracheal tubes (Parker Medical, Highlands Ranch, CO) with a curled distal tip, to avoid injury to the vocal cords, useful for reintubating the patient through the mouth, if necessary during the conduct of the operation. The sterile draping should be done in a manner, which allows the anesthetist to visualize the operative field as much as possible.

INCISIONS

The surgical approach is dictated by the location and extent of the tracheal damage, and whether or not the resection is for benign or malignant conditions. For most lesions involving the subglottic region or upper half of the trachea, a cervical incision is usually adequate. In a patient with reasonable neck extension and normal elasticity of the trachea, benign lesions even at the mid-tracheal level can usually be managed through the cervical incision.

VENTILATOR MANAGEMENT DURING TRACHEAL RESECTION AND RECONSTRUCTION

Prior to induction of general anesthesia, topical anesthesia to the nasopharynx is administered and bronchoscopic assessment of vocal cord function is carried out as well as visualization of the damaged segment of the trachea. If there is a tight stricture present, it is dilated with gradually increased sizes of rigid bronchoscopes to allow passage of an endotracheal tube, preferably a size 5 or larger.

CERVICAL TRACHEAL RESECTION WITH END-TO-END ANASTOMOSIS

The patient is positioned supine with an inflatable pillow beneath the shoulders (Fig. 9.8). The head is extended as much as possible. A curved-collar incision is made one to two fingerbreadths above the sternal notch and superior and inferior subplatysmal flaps are raised. The strap muscles are separated in the midline. Blunt dissection separating the more superficial sternohyoid muscle from the underlying sternothyroid muscle on either side may improve the ability to retract the strap muscles out of the way.

If a tracheostomy stoma is present, the collar incision is made at the level of the stoma and an ellipse of skin is taken with the stoma. The anterior surface of the
Fig. 9.8. The patient is positioned supine with an inflatable pillow beneath the shoulder. The head, which is positioned at the very upper end of the table, is supported by a ring cushion and is extended.

trachea is exposed below the stoma and blunt finger dissection is carried down as far as possible towards the carina being especially careful not to injure the innominate artery which, if high-riding, may be above the sternal notch. The anterior surface of the trachea is then cleared superior to the tracheostomy stoma, up to the cricoid cartilage.

If no current or previous tracheostomy stoma site is present following separation of the strap muscles, the anterior surface of the trachea is cleared with blunt finger dissection from the larynx down to the distal trachea.

In the case of a cuff stricture caused by a previous tracheostomy, the identification of the stricture site is usually obvious from the external scarring and narrowing of the trachea. In some instances, especially with strictures caused by previous, brief, endotracheal intubation the damage to the tracheal wall at the site of the stricture may not be obvious from external inspection of the trachea. In this case, a flexible bronchoscope is placed down the endotracheal tube, the endotracheal tube is withdrawn to the subglottic position, the stricture is endoscopically identified, and a 25-gauge needle is passed by the surgeon through the anterior tracheal wall into the tracheal lumen as a reference point to determine the exact position of the stricture, which is then marked with placement of a stitch through the anterior tracheal wall.

Traction sutures placed in a mid-lateral position on either side are helpful not only for the subsequent reduction of tension when doing the anastomosis but also for rotating and elevating the trachea from side to side when dissecting out the damaged section of the trachea. These are full thickness sutures of either 2-0 silk or 2-0 polyglactin (vicryl) placed around one or two rings. These are placed beyond the anticipated limits of resection, and then tied down to the trachea to prevent back-and-forth sawing of the sutures through the wall of the trachea as they are being manipulated.

The lateral dissection of the trachea is then carried out at the level of the lesion, staying very close to the tracheal wall to avoid injury to the recurrent laryngeal nerves. It is not necessary to actually identify the nerves if the dissection is kept on the tracheal wall. The lateral dissection should be done only for the distance that is necessary to encompass the anticipated segment of trachea to be resected. The use of a fine-tipped bipolar cautery for cauterizing blood vessels close to the trachea is useful to help avoid injury to the adjacent recurrent laryngeal nerves. Once the trachea has been divided and the ends are trimmed back, further lateral dissection can be done if necessary.

Division of the trachea can be done in one of two ways. Formerly, the recommendation was to completely encircle the trachea separating the membranous wall of the trachea from the underlying esophagus just distal to the segment of tracheal damage where the scarring is less and the ability to safely separate the trachea from the esophagus is easiest. Often this separation is difficult and there is concern about injury either to the underlying esophagus or damage to the membranous wall of the trachea at a site that might otherwise be suitable for the anastomosis. For benign lesions, division of the trachea at the site of the stenosis is now favored. Using this technique, the trachea is dissected laterally on either side of the lesion down to the junction between the cartilaginous and membranous wall on either side. Then the cartilaginous portion of the trachea is transected transversely sparing the membranous wall.

Once the anterior wall of the trachea has been divided until its tip is visible in the airway and then a heavy traction suture is passed through the tip of the endotracheal tube to facilitate its re-advancement later in the procedure. A high-frequency jet catheter is inserted through the endotracheal tube from above, and the tip is passed into the distal trachea for continued ventilation during completion of the tracheal transection. This improves the visualization of the posterior wall of the airway (Fig. 9.9A). Alternatively, a sterile endotracheal tube can be inserted into the distal trachea and attached to sterile corrugated anesthesia tubing, which has previously been passed through the operative field to the anesthesiologist. In this situation, periodic removal and replacement of the endotracheal tube is used for intermittent ventilation until the trachea has been completely divided and the distal portion mobilized.

The membranous wall is then transected from the inside with a scalpel, tenting the trachea up with the traction sutures. Once transected, the membranous wall of the trachea is separated from the esophagus at either end of the divided trachea. Following this, the trachea is trimmed back proximally and distally to reach satisfactory margins for the primary anastomosis. A small bougie (e.g., size 36 Maloney dilator) may be placed in advance into the esophagus to help identify the esophagus and facilitate separation of the back wall of the trachea from the esophagus.

Once the resection has taken place and the sutures are to be placed in the posterior membranous wall, a jet ventilation catheter can be placed across the operative field into the distal trachea end and used for jet ventilation (Fig. 9.9B). This gives good visualization of both ends of the membranous trachea while the sutures are placed without having to repeatedly insert and remove an endotracheal tube into the distal trachea.

The posterior wall of the anastomosis involving the membranous trachea is carried out first using 4-0 vicryl sutures. The technique proposed by Grillo involves placement of the sutures with the knot to be tied on the outside of the lumen after all of the other anastomatic sutures have been placed and tied. I prefer placement of the sutures with knots on the inside, tying all of the membranous wall sutures initially, using the superior and inferior traction sutures to take tension off the anastomosis
with the endotracheal tube advanced into the distal trachea for continued ventilation while the membranous wall of the trachea is transected. Then, in the case of a benign stricture, serial transverse incisions are made through the damaged segment until reaching a level satisfactory for anastomosis and the membranous wall is again transected at that level, completing the resection. (B) Following resection, the posterior (membranous) portion of the anastomosis is completed with interrupted absorbable sutures using the jet-catheter for continued ventilation.

Fig. 9.9. (A) After the cartilaginous portion of the trachea has been transected, the endotracheal tube is partially withdrawn so that its tip is proximal to the lesion for improved visualization of the airway. The high frequency jet-catheter is passed down the endotracheal tube across the field and into the distal trachea. (B) After the cartilaginous portion of the trachea has been transected, the endotracheal tube is partially withdrawn so that its tip is proximal to the lesion for improved visualization of the airway. The high frequency jet-catheter is passed down the endotracheal tube across the field and into the distal trachea. The cartilaginous sutures, using 4-0 polyglactin (vicryl), are placed with knots to be tied on the outside. They are placed sequentially working from the posterior to the anterior portion of the trachea on either side and are left untied until all have been placed.

After the sutures have been placed into the cartilaginous portion of the anastomosis on either side the endotracheal tube, which had been withdrawn into the larynx, can be advanced into the distal trachea to provide ventilatory support while the remaining sutures are placed. Alternatively, the jet catheter can be used for this portion, but once the anastomosis has been nearly completed, ventilation through the jet catheter is unsatisfactory as most of the ventilatory volume from the jet catheter involves entrained air through the open trachea. Once the opening of the tracheal wall is closed, it is best to ventilate the patient with the endotracheal tube advanced into the distal trachea with its cuff placed well beyond the anastomosis.

Once the anastomotic sutures have been placed and are ready to be tied, the inflatable bag is deflated, the extended head brought forward by the anesthesiologist, and the proximal and distal traction sutures on either side are pulled together to avoid tension when tying the sutures.

In most cases, the traction sutures are usually removed following completion of the anastomosis. In cases where tension on the anastomosis is a concern, the superior and inferior traction sutures on either side can be tied to each other and left in place.

The anastomosis should be covered, if possible, with surrounding tissue. Often the thyroid isthmus has been divided as part of the dissection, and the isthmus can then be reconnected over the anastomotic site. Otherwise, the strap muscles can be used.

A ¼-inch Penrose drain is placed in subcutaneous space on either side and brought out through the corner of the incision as a blood drain. This is removed on the first postoperative day.

At the end of the procedure, the endotracheal tube is withdrawn and replaced with a laryngeal mask allowing flexible bronchoscopy through the laryngeal mask to assess the anastomosis and also allowing for visualization of vocal cord function as the patient awakens from the anesthesia. The operative field remains sterile at this time so that if a protective tracheostomy is deemed necessary, it can be performed below the anastomosis. The need for this is very uncommon with segmental trachea resections but may be necessary after complex laryngotracheal resections, as subsequently described.

Following closure of the wound, a No. 2 monofilament polypropylene suture is placed transversally through the submental skin and then passed transversally deeply through the skin in front of the manubrium. This tethering suture, designed to protect the patient from inadvertent hyperextension in the postoperative period, is placed while the patient is still under light anesthesia but left untied until the patient is breathing spontaneously. It is then tied with the head in slight flexion.

**SUBGLOTTIC RESECTION AND LARYNGOTRACHEAL ANASTOMOSIS**

Resection of the subglottic airway is most commonly required for idiopathic subglottic stenosis and for postintubation injury affecting the region of the cricoid and upper trachea. It may also be required for the treatment of traumatic injuries including cricoid fractures and laryngotraheal separation and for occasional tumors involving the cricoid cartilage.

For this procedure, the anastomosis often must be placed within several millimeters of the vocal cords. Avoiding injury to the recurrent laryngeal nerves is accomplished by resection of the anterior portion of the cricoid cartilage and reaming out of the posterior cricoid plate, or lamina, with preservation of its posterior perichondrium as the nerves are located posterior to the posterior cricoids lamina. The most common source of postintubation injury to the subglottic area is a high tracheotomy site placed inadvertently through, or just inferior to, the cricoid cartilage, or placed there during the performance of an emergency tracheostomy in a life-threatening situation. In addition, such a high placement can occur during an elective tracheostomy in a patient with adverse anatomy such as significant cervical kyphosis, obesity, or other conditions limiting access to the trachea at the level of the second or third rings. As a result of the high tracheotomy placement, the cricoid arch is either directly injured or subsequently eroded into by the tracheotomy tube. With such an injury caused by a high tracheostomy, it is not uncommon for patients to present with a tracheostomy tube in place accompanied by complete obliteration of the subglottic airway just above the tube (Fig. 9.10). In such cases, it may be possible to reestablish an airway.
This 23-year old male suffered a spontaneous sub-arachnoid hemorrhage and was intubated with an endotracheal tube for several days. Following discharge to a rehabilitation center he developed increasing stridor and subsequently underwent emergency tracheostomy. Subsequent assessment, shown here, demonstrated complete obliteration of the subglottic airway. The patient underwent laryngotracheal resection with primary anastomosis using rigid bronchoscopic techniques and dilatation followed by placement of a silicone T-tube to temporarily stent the subglottic stricture. This allows the patient to speak and breathe through the upper airway permitting humidification of inspired air. Just as a highly placed tracheostomy can lead to considerable inflammatory changes in the subglottic region, so too can repeated application of laser ablation and endoluminal dilatation in a patient with idiopathic subglottic stenosis. This may prevent or significantly complicate subsequent surgical management of the subglottic stricture. An occasional patient with idiopathic subglottic stenosis may be managed with periodic dilatation, steroid injection, and mitomycin injection, but the natural history of the condition is one of decreasing intervals between the need for repeated dilatation. Such patients should be considered for surgical resection after no more than two or three attempts at endoscopic management.

Operative exposure for a laryngotracheal resection is similar to that for standard cervico-tracheal resection. The operative field should be prepped and draped up to the chin, as exposure of the hyoid bone may be necessary for a complementary suprahyoid laryngeal release procedure. If a tracheostomy tube is in place, and there is no airway passage remaining through the strictured airway to allow intubation through the mouth, then an armored endotracheal tube is substituted for the tracheostomy tube and prepped into the field. Following exposure of the larynx and anterior trachea, the lateral portion of the trachea at the level of the first tracheal ring is dissected back to the membranous wall of the trachea on either side taking great care to stay directly on the tracheal cartilage to avoid injury to the recurrent laryngeal nerves. Only bipolar cautery should be used in this region. A horizontal incision is made through the perichondrium of the cricoid ring from one mid-lateral position to the other and the perichondrium peeled back proximally and distally to expose the cartilage. It is not uncommon for the cartilage to be calcified in such patients. The anterior half of the cricoid is then removed, saving intact for the moment the perichondrium behind the cricoid ring. Following this, the anterior wall of the airway is incised with a scalpel generally through the bed of the cricoid which is also likely an area of dense scarring and airway narrowing (Fig. 9.11). The transaction of the airway is then carried down in an oblique manner on either side to reach the junction between the inferior rim of the cricoid lamina and the membranous wall of the first tracheal ring just inferior to the cricoids lumina. This gives good exposure of the posterior tracheal wall, allowing it to be carefully transected with a scalpel, from the inside of the partially divided airway.

In our early experience, the recurrent laryngeal nerves were carefully identified at this point, as they traveled cephalad from the tracheoesophageal groove on either side to ascend behind the posterior cricoid lamina. More recently, however, no attempt is made to identify the nerves, and the dissection of the lateral tracheal wall and transection of the posterior wall is done carefully to keep dissection posterior to the cricotracheal junction to a minimum. Once the trachea has thus been completely transected, upward traction on the distal cut end of the trachea permits careful dissection of the trachea from the esophagus. In most cases, when there has been an existing tracheotomy in place at the time of the operation, the tracheostomy site in the trachea is excised as well. However, in some cases, the stoma may be left in place if there is sufficient trachea proximal to the stoma to permit a satisfactory anastomosis without...
the need to resect the additional tracheal length necessary to excise the segment of the trachea containing the stoma.

Once airway division has occurred, the posterior cricoid lamina is reamed out between its anterior and posterior perichondrial layers. This can be done with a pituitary rongeur, a dental burr, or a curette depending on the circumstances. This removal of a portion of the posterior cricoid lamina basically provides a recess behind the airway mucosa and perichondrium, which can be carried up for as much as 1½ to 2 cm (Fig. 9.12). Any advancement beyond this point risks injury to the cricoarytenoid joints, which are on the cephalad border of the cricoid lamina. The anterior airway, essentially the cricothyroid membrane, and the posterior membrane, the mucoperichondrial flap provided by the coring out of the posterior cricoid lamina, are then sharply trimmed with a scalpel up to the point where the tissue is as healthy as possible, still permitting a primary anastomosis just inferior to the vocal cords. Clearly, the vocal cords present an upper limit to such excision and to avoid injury to them, it may not be possible to excise back to entirely normal tissue especially if the injury extends up into the conus elastica below the superior borders of the vocal cords.

Exposure for the posterior dissection of the subglottic airway and placement of the posterior anastomotic sutures may be facilitated with the use of an anterior midline laryngofissure. Ordinarily, a complete anterior laryngofissure is carried out, but for this procedure an incision of the lower two-thirds of the laryngeal cartilage, preserving the anterior vocal process, may be sufficient to avoid injury to the anterior vocal cord attachment while still providing excellent exposure (Fig. 9.13).

Once both the upper and lower resection margins have been defined and prepared, the amount of tension on the anastomosis is evaluated by deflation of the inflatable cushion behind the shoulders, flexion of the head by the anesthesiologist, and upward traction of the trachea using the lateral traction sutures. If it appears that the tension on the anastomosis will be excessive, then a suprahypoid laryngeal release is employed as subsequently described. If it is apparent from the outset that adequate resection of the subglottic stenosis will likely result in significant tension, then the laryngeal release can be done prior to the division of the airway.

The tracheal end of the anastomosis is usually done utilizing the full circumference of the trachea; however, if there is excessive discrepancy between the subglottic airway and the trachea, the tips of the cartilaginous ring at the end of the divided trachea can be brought together with one or two side-to-side stitches imbricating the membranous wall and creating a complete cartilaginous ring, as described by Pearson in the initial report of laryngotracheal resection procedure (Fig. 9.14). Grillo subsequently described a modification in which the uppermost cartilaginous ring of the divided trachea was excised, leaving the associated membranous portion of this segment intact thus creating a posterior mucosal flap for anastomosis to the posterior laryngeal mucosa while the remainder of the tracheal portion of the anastomosis is done through the cartilaginous portion of the uppermost tracheal cartilage.

If the posterior wall of the anastomosis on the laryngeal side involves thickened or inflamed tissue, or is well up into the larynx, the posterior portion of the anastomosis may be carried out with fine stainless steel wire (34 gauge) to provide a strong, inert suture line in this narrow portion of the upper airway. This reduces the chances or postoperative granulation tissue that may form if absorbable sutures are utilized. Alternatively, absorbable sutures (4-0 vicryl) may be placed in a manner such that the knots are to be on the outside of the lumen but tied from the inside, as described by Montgomery, reducing the likelihood of granulation tissue.

When the anterior wall of the airway at the laryngeal end is being prepared, it may be trimmed back to the inferior border of the laryngeal cartilage and the laryngeal cartilage used for the anastomosis. However, preserving a small fringe of the cricothyroid membrane, inferior to the laryngeal cartilage, may facilitate matching up the size of the tracheal end of the anastomosis with the laryngeal end of the anastomosis.

After the posterior sutures have been placed and subsequently tied, the lateral sutures on either side are then placed and tied. The endotracheal tube can be advanced into the distal trachea and the remaining sutures placed and tied using 4-0 absorbable vicryl sutures.

As previously described following cervical tracheal resection with end-to-end anastomosis, it is useful to substitute a laryngeal mask for the endotracheal tube.
after the anastomosis has been completed and the wound is being closed. This permits the assessment of vocal cord function and of anastomotic patency. If there is any concern about the safety of the airway, a mini-tracheostomy or small cuffed tracheostomy may be placed below the airway anastomosis. Rarely, following completion of the anastomosis, a silicone T-tube may be placed through a tracheostomy stoma with the upper limb of the T-tube extending through the anastomotic region to a point just below the vocal cords. This is done if, having extended the proximal resection as high as safely possible, it is recognized that the mucosa at the proximal end of the anastomosis is thickened, scarred, or inflamed.

The “guardian” chf suture is placed but left untied until the patient is fully awake, the airway is found to be satisfactory, and the patient is about to leave the operating room.

RESECTION OF DISTAL TRACHEAL LESIONS

For resection of a distal tracheal lesion, either a median sternotomy or a right posterolateral thoracotomy approach may be used. For benign conditions such as stricture or for a malignant tumor that appears confined to the airway without significant extratracheal extension, the median sternotomy provides excellent exposure and may prove technically less demanding than a posterolateral thoracotomy. For bulky tumors or tumors that may have a posterior extension involving the esophagus, a right thoracotomy is preferred. Both approaches permit a hilar release procedure, when necessary to reduce tension on the anastomosis. For the trans-sternal approach, a single-lumen endotracheal tube is usually satisfactory with the availability of a sterile set of tubing on the operative field for intubation of the distal trachea or one of the main bronchi. In addition, provision for jet ventilation through the endotracheal tube from above or across the operative field should be made. If a right thoracotomy approach is chosen, then a left-sided double-lumen tube should be employed if the airway lumen will allow its passage. Otherwise, a long endotracheal tube directed into the proximal left main bronchus under bronchoscopic control should be placed. In this situation, inflating the cuff will provide for left lung ventilation with isolation of the right lung, while deflation of the cuff and packing the pharynx with a wet gauze provides for direct ventilation of the left lung and indirect ventilation of the right lung. Following dissection of the airway via a right thoracotomy, it is important to keep in mind that when encircling the distal trachea care must be taken to avoid injury to the left recurrent laryngeal nerve, which may be difficult to visualize. Keeping the dissection on the wall of the trachea and as close to the carina as possible will help avoid injury to the nerve.

If a right thoracotomy is being used for the resection of a malignant tumor, the operation often begins with a mediastinoscopy and assessment of the extent of the tumor and any possible spread to mediastinal lymph nodes, which may contraindicate proceeding with the resection. If the mediastinoscopy findings support proceeding with the tracheal resection, then it is helpful to dissect the left recurrent laryngeal nerve away from the lateral wall of the distal trachea and tracheobronchial angle with blunt dissection creating a free plane between the trachea and the nerve. This greatly facilitates safe encirclement of the distal trachea through the subsequent right thoracotomy exposure.

When the sternotomy approach is used, the sutures for the posterior, membranous wall of the anastomosis are the first to be placed and tied followed by advancement around both sides of the cartilaginous trachea and finally completing the anterior portion of the anastomosis. When done through the right thoracotomy, the “far” sutures, involving the left lateral trachea wall, are the first to be placed and subsequently tied with knots on the inside followed by the remainder of the anastomosis.

RELEASE PROCEDURES FOR DECREASING TENSION ANASTOMOSIS

Suprahyoid Release

Release of the superior attachments of the larynx, as part of a tracheal resection, may increase the limits of safe resection by providing additional “length” and thus avoiding undue tension on the suture line. This maneuver is most commonly used for laryngotraacheal and cervico tracheal resections if there appears that there will be significant tension at the level of the anastomosis. It is usually required if 5 cm or more of trachea is to be resected. It should be performed, in general, prior to the completion of the anastomosis since the release will help determine how much of the airway can be resected without undue tension. Most commonly during the resection, the inferior and superior margins are progressively extended intermittently pulling the two ends of the airway together to estimate anastomotic tension before deciding the balance between further excision versus the risk of increasing anastomotic tension and the complications, which may result. For the laryngeal release, the suprahyoid procedure described by Montgomery is preferred as it is associated with a lesser risk of postoperative pharyngeal dysfunction and aspiration than the infrahyoid release.

Montgomery’s original description of this release utilized a large “U”-shaped skin incision with creation of a large skin flap extending upward from the inferior aspect of the incision just above the sternum notch up almost to the mandible on either side. This is the same incision that is ordinarily used for laryngectomy. We have found such a flap unnecessary and instead utilize a small separate transverse incision made directly over the hyoid bone (Fig. 9.15A). It is important, however, to dissect the subplatysmal plane between the initial inferior cervical incision and the hyoid incision in order to make certain that the larynx is completely released from its subcutaneous attachments to assure maximum descent following the release.
After the hyoid bone has been exposed, a needle-point cautery is used to divide the muscle attachments from the superior surface of the hyoid bone from a point just lateral to the inferior cornu on one side to a similar point on the other side. These muscle attachments include the mylohyoid, geniohyoid, and genioglossus muscles. The lesser cornua of the hyoid bone are identified by palpation and cut from their attachment to the hyoid bone. These maneuvers expose the pre-epiglottic space. The hyoid bone is then transected with a small bone cutter on either side just lateral to the lesser cornua (Fig. 9.15B). With downward traction on the mobilized anterior segment of the hyoid, the pre-epiglottic space is further dissected to give maximum release taking care not to breach the mucosa (Fig. 9.15C).

### Intrathoracic (Right Hilar) Release

The right hilar release maneuver is most commonly employed in conjunction with a major resection of the mid or distal trachea or carina but may also rarely be used for an airway anastomosis following a right upper lobe sleeve resection or a bilobectomy with reattachment of the lower lobe bronchus to the right main bronchus.

The hilar release can be performed through the median sternotomy or through a right thoracotomy approach. The inferior pulmonary ligament is mobilized and the pericardium anterior to the inferior pulmonary vein is incised about 1 cm anterior to the vein. This incision is carried inferiorly in a curved manner toward a point just inferior to the pulmonary vein. A similar incision is made posterior to the inferior pulmonary vein and joins the previously made anterior incision to form a U-shaped incision around the lower half of the pulmonary vein. The actual release procedure involves intrapericardial incision of the fibrous connection between the inferior vena cava and the pericardium. This connection is the distal extension of the interatrial groove. Using a Kocher clamp the midpoint of the cut edge of the pericardium below the vein is grasped, and using scissors inside the pericardium, the septum between the inferior vena cava and the inside of the pericardium is carefully incised down toward the diaphragm as far as possible. This release then allows the right lung and its attachment to the atra to be retracted upward (Fig. 9.16). The pericardial release can be carried more superiorly by extending the pericardial incisions superiorly toward the pulmonary artery and when used to its maximum extent may involve freeing up the right pulmonary artery from its pericardial attachments as well.

### Postoperative Management

Following completion of a tracheal resection, the patient is allowed to awaken and is extubated while in the operating room. During this time, the instrument table should remain sterile, a flexible and rigid bronchoscope should be ready,
and a tracheostomy kit should also be readily available. As previously noted, the endotracheal tube is removed and a laryngeal mask is substituted as the patient is emerging from anesthesia. Through this mask a flexible bronchoscope is utilized to assess the anastomosis, clear the secretions from the airway, and assess vocal cord function as the patient awakens. A decision is then made as to whether or not a protective tracheostomy is required. If so, a small endotracheal tube can be inserted with the cuff placed distal to the anastomosis or ventilation can be maintained with a laryngeal mask. If a tracheostomy is to be inserted, this is ideally done with a small opening in the trachea 1 to 2 cm distal to the anastomosis. If the procedure has been very long and complicated and there is a question of needing ventilatory support postoperatively, then a cuffed tracheostomy tube is utilized. Otherwise, a noncuffed, or a so-called, “mini-tracheostomy” tube is utilized for airway protection.

The patient should be observed for the first few hours in the postoperative recovery area, readily accessible for periodic observation by the surgeon and anesthesiology staff before transfer to the nursing unit. The patient is initially placed in the supine position with the head of the bed elevated to reduce edema. To minimize edema a dose of methyl prednisone sodium succinate, 125 to 250 mg, may be administered intravenously toward the end of the operation. Diuretics may also be employed to reduce postoperative edema, and a tank of heliox (30% O₂ to 70% He) should be available for administration through a mask, if there is stridor. Nebulized racemic epinephrine may also be administered via face mask in the recovery room.

Oral intake should be withheld until at least the second postoperative day assuming that both vocal cords are working normally. If there is vocal cord paralysis, a longer period without oral intake may be necessary to minimize the risk of aspiration that is particularly likely to occur when the combination of vocal cord palsy, laryngeal edema, and restriction of laryngeal elevation secondary to the resection coexist. Oral intake is generally begun with Jell-O, which is more easy for the patient to handle than liquids, and which, if aspirated, is nonirritating and easily coughed up. Once the patient has demonstrated the ability to swallow Jell-O without difficulty the diet is advanced. The patient is usually ambulatory by the first postoperative day. The chin stitch is left in place for 1 week and removed prior to the patient’s discharge. In the absence of any concern regarding upper airway compromise, postoperative bronchoscopy is not routinely employed prior to discharge.

### Complications

The most common complications following tracheal resection include vocal cord dysfunction, superficial wound infection, and anastomotic complications that include both early separation of the anastomosis and late recurrent stenosis. Obstructing granulation tissue is not uncommon and may be treated with endoscopic cauterization, bronchoscopic debridement, or balloon dilatation.

The wound should be left undressed starting on the first postoperative day and inspected once or twice daily. At the earliest signs of wound infection, the neck incision should be partially opened and packed to avoid deep infection, which can affect the suture line. Wright et al. reviewed the results from the Massachusetts General Hospital following tracheal resection in 901 cases over a 20-year period primarily comprising the experience of Grillo. Successful results were reported in 95% of patients with anastomotic complications occurring in 9% and with an overall perioperative mortality of 1.2%. The risk factors found to be associated with anastomotic complications included diabetes, the need for reoperation, resections >4 cm, the need for a tracheostomy prior to operation, and laryngotracheal resection. Anastomotic complications, especially stenosis and granulation tissue, may resolve with repeated dilatation but if a tight stricture ultimately results, then insertion of a silicone T-tube or the use of a tracheostomy tube distal to the anastomosis probably should be placed. If anastomotic narrowing of significant degree occurs in the first month or two injections of steroids seems to be of limited value, though one or more anastomotic dilatations coupled with a course of oral steroids for several weeks, may allow for resolution. In our experience, the most challenging and complicated procedures tend to be in those patients with postintubation injury to the subglottic region resulting in total or near-total obstruction.
obliteration of the airway at the level of the cricoid cartilage. Such patients have multiple risk factors, as identified by Wright, including major comorbidities associated with the original need for the ventilator assistance that led to the airway injury in the first place. Most of these patients have had a tracheostomy tube placed to provide a safe airway in advance of the laryngotracheal resection. In more than half of such patients, a suprathyroid laryngeal release was required and a protective tracheostomy was also placed at the completion of the resection. One patient required a T-tube. In this challenging group, 11 of 14 patients had an excellent outcome with one postoperative death.

Another group of patients at higher than usual risk for postoperative complications are those with idiopathic subglottic stenosis who have been subjected to repeated dilation and/or laser procedures resulting in extensive scarring in the subglottic region. It is for this reason that laryngotracheal resection is advised after one or two endoscopic procedures at most have been attempted, especially if the interval between the intervention and the subsequent recurrence of symptoms is limited.

**CONCLUSION**

Postintubation stricture is the most common indication for tracheal resection. This is especially true if there has been traumatic initial intubation, emergency tracheostomy, or a high tracheostomy, which is adjacent to, or involves the cricoid cartilage either by inadvertent malpositioning or because the weight of the patient, curvature of the spine, or other physical factors make it difficult or impossible to place a tracheostomy tube in the usual position.

Resection of postintubation strictures should be delayed until the patient is in optimal condition using such temporizing maneuvers as repeat dilations, insertion of a T-tube, or use of a tracheostomy tube. The importance of a skilled thoracic anesthesiologist as a member of the operative team cannot be overemphasized. Generally, excellent outcomes with low morbidity and mortality rate can be achieved.

**SUGGESTED READINGS**

---

**EDITOR’S COMMENTS**

The average thoracic surgeon during an entire career will likely see very few patients requiring tracheal resection and thus expertise is hard to develop. A few centers and, for that matter, a few surgeons have dominated this area and we must pay homage to both the late Hermes Grillo and to F. Griffith Pearson for their significant contributions to this field. Dr. Cooper himself also has made significant contributions to surgery of the trachea having worked with both Drs. Grillo and Pearson.

The diagnosis of a tracheal obstructing lesion often is delayed with the patient being told either by their primary care physician or a pulmonologist they have “asthma.” The key is recognizing that these patients have a wheeze with inspiration, a finding that differentiates the problem from reversible airways disease. A simple flow-volume loop essentially makes the diagnosis, and patients should not have to experience almost complete airway obstruction before a diagnosis is made. Patients who present with an obstructing lesion can be temporized by simple deb­ulking of the tumor done with the rigid bronchoscope. This assumes, of course, that the thoracic surgeon is facile with rigid bronchoscopy, an art that I am afraid is not being taught to any great extent in most residency programs today.

Tracheal stenosis resulting from prolonged endotracheal intubation is usually related to ischemia caused by an overinflated tracheal cuff. More attention is being paid to cuff inflation and we are more aggressive about performing tracheostomy in the patient requiring prolonged ventilator support so fewer of these lesions are being seen. Essentially, all of these are located in the upper to mid-trachea and can be approached via a cervical incision. As pointed out, care must be taken to preserve the segmental blood supply to the trachea by only circumferentially mobilizing in the area to be resected. Often the stenosed area must be defined bronchoscopically and a needle placed for localization to guide the resection. Sufficient trachea must be resected so that normal tracheal lumen is present. The inexperienced tracheal surgeon may be hesitant to take the amount of trachea required because of fear of not being able to put the airway back together so a stenotic portion is left, a result that is doomed to failure. Any surgeon who undertakes a tracheal resection must be familiar with the various release procedures as well as limits of resection.

Subglottic tracheal stenosis requires special expertise and really should only be undertaken by those experienced in these resections. Often the collaboration with a head and neck surgeon facilitates the dissection especially if a laryngofissure is required for optimal exposure. Injury to one or both recurrent laryngeal nerves can be disastrous and must be avoided at all costs but adequate resection must be accomplished as a revision procedure is fraught with a higher incidence of morbidity. Working in the subglottic area is not for the faint of heart.

Distal tracheal resection, as noted, may be approached via right thoracotomy or median sternotomy and the decision rests with surgeon experience as well as lesion location. Both approaches allow excellent exposure of the carina but in my (continued)
experience the right thoracotomy offers somewhat better exposure to the proximal left main bronchus.

I favor using an armored tube and sterile anesthesia tubing ventilating periodically once the airway is divided over the use of jet ventilation. There is usually ample time dictated by the oxygen saturation level to allow for suture placement during the period when the patient is not being ventilated. Too many times I have seen the jet ventilation catheter propel itself out of the airway for me to be comfortable with that technique.

The placement of the chin stitch remains an important adjunct preventing the patient from significantly extending the neck. The stitch should be loosely placed only serving as a reminder, not something punitive.

LRK
INTRODUCTION

Carinal resections are some of the most technically challenging procedures in thoracic surgery and should be approached with great attention to detail. The preoperative evaluation should include a complete medical workup, oncologic staging, and careful operative planning from the surgical and anesthesia perspectives. Of paramount importance is the creation of a secure, well-vascularized anastomosis under minimal tension. A vast majority of carinal resections are performed for malignancies, but occasionally benign conditions can result in critical airway obstruction that mandates a carinal resection. Despite the high incidence of morbidity associated with these procedures, 1-year survival for malignant disease as high as 75% has been reported. Survival is significantly shorter in patients with resectable lesions and is usually measured only in months.

PATIENT EVALUATION

The workup of a patient with a carinal mass is not dissimilar from the workup for routine lung cancer patients. Involvement of the carina by lung cancer histology is considered a T4 lesion. Careful attention to a complete oncologic staging as well as appropriate medical and cardiopulmonary clearance is mandatory. Patients should undergo cardiac clearance and pulmonary function testing especially in situations in which concomitant pulmonary parenchymal resection will be required. Consideration of comorbid conditions and assessment of nutritional status is required. Many patients with tracheal lesions that result in respiratory compromise are placed on steroids during their diagnostic workup and it is important to wean the patients either completely off steroids or to as low a dose as possible prior to the elective resection and reconstruction. Smoking cessation is also important to optimize healing of the airway anastomoses and facilitate secretion clearance in the postoperative period.

Common diagnoses associated with carinal resections are listed in Table 10.1.

Computed tomographic (CT) scans are an essential part of the evaluation of tracheal lesions in patients who may require a carinal resection. CT provides information regarding the estimated length of the tracheal wall involvement and the endoluminal and extraluminal extent of disease. CT imaging can evaluate the size, shape, and number of mediastinal lymph nodes in the paratracheal, subcarinal, and supraclavicular stations. Pulmonary nodules suspicious for metastatic disease can also be detected. If available, 3D reconstructions based on CT images may help with operative planning (Fig. 10.1A and 10.1B). We use total body positron emission tomography (PET) fused with CT (PET/CT) and magnetic resonance imaging (MRI) of the brain to complete the staging workup for distant metastatic disease. The finding of distant metastatic disease, of course, is a contraindication to resection.

Bronchoscopy is a mandatory component of the evaluation of patients being considered for a carinal resection. Flexible bronchoscopy can be used to biopsy the lesion as well as assess the proximal and distal extent of the airway involvement. Rigid bronchoscopy using the tip of the bronchoscope to core through the tumor is useful to debulk obstructing lesions in a patient who presents with critical airway obstruction. This can quickly reestablish a patent airway with minimal bleeding in most cases. Lasers, argon plasma coagulators, and electrocautery techniques can also be used particularly for the more vascular tumors to control any bleeding if this should be encountered. Rigid bronchoscopy is also helpful to perform detailed measurement of the lesion, as well as assessing tumor fixation to the tracheal wall and overall tracheal mobility in relation to other mediastinal structures.

Mediastinal staging is required in these patients. N2 or N3 disease is difficult to characterize because of the central nature of these lesions, but we usually assign laterality based on the predominant involvement of the main stem bronchi. Patients demonstrating involvement of the mediastinal lymph nodes most commonly are treated with nonsurgical modalities (T4N2/N3 stage IIIB disease).

Endobronchial ultrasound (EBUS) offers additional diagnostic information in these patients. We use EBUS to obtain samples of lymph nodes for staging purposes at levels 2, 4, 7, and 11. In some cases we have also employed radial probe ultrasound to assess both the depth and extent of tracheal wall invasion.

We reserve the use of mediastinoscopy at the time of formal resection and favor EBUS for diagnostic purposes in the preoperative period. We do not recommend mediastinoscopy and a delayed carinal resection, as scar tissue that may compromise tracheal mobility at the time of resection will develop in the pretracheal plane in the time between the two procedures.

ANESTHETIC MANAGEMENT

A successful carinal resection requires excellent communication between the thoracic surgeon and an experienced thoracic anesthesiologist. For the safe conduct of the procedure, the anesthesiologist must be facile with multiple modes of ventilation, the performance of intraoperative bronchoscopy, and be committed to the planned extubation of the patient in the operating room suite immediately at the completion of the procedure. Immediate postprocedure extubation should be the goal of all team members; therefore, short-acting agents and careful fluid management are particularly important especially in situations where lung parenchyma resection is also planned, as in a carinal pneumonectomy.

The airway should be managed initially with an extra-long reinforced single-lumen tube that is placed with fiberoptic guidance. This will minimize trauma to

the airway and to the tumor itself so as to avoid hemorrhage into the distal airway. The extra-long tube (usually #7) provides a significant advantage in that it can be positioned in the trachea or bronchoscopically guided into the left or right main stem bronchus depending on the tumor location and the operative approach. The use of a double-lumen tube is not recommended as the tube is bulky and not easily maneuvered intraoperatively.

Prior to any incision in the airway, a focused discussion and simulation of the airway management between the surgeon and the anesthesiologist will ensure patient safety. A sterile reinforced endotracheal (ET) tube with extension tubing and appropriate and tested connectors is passed from the surgical field to allow for cross-table ventilation, prior to an airway incision. Once the airway has been opened, the sterile tube is placed into one of the main stem bronchi for ventilation. Throughout the resection and creation of the anastomosis it may be necessary to intermittently remove the ET tube from the airway to facilitate suture placement. During these periods of intermittent ventilation, hand ventilation by the anesthesiologist may be the best way to maintain oxygen saturation, prevent hypercarbia, and avoid barotrauma to the ventilated lung. In patients who do not tolerate intermittently ventilation, it may be necessary to use high frequency jet ventilation techniques. The surgeon and anesthesiologist, however, must be aware of the risks of air trapping and barotrauma associated with this method of ventilation.

In patients who present emergently with near-obstructing tracheal lesions, the use of cardiopulmonary bypass (CPB) or extracorporeal membrane oxygenation (ECMO) systems has been described. Perfusion cannulas can be placed under local anesthesia prior to the induction of the general anesthetic in these patients who present in extremis. Centers who have described these techniques show comparable morbidity and mortality to more traditional approaches. The use of rigid bronchoscopy to core out and debulk the tumor, however, in most cases will eliminate the need and risks of CPB and will convert an emergent procedure into an elective resection. This is a lifesaving skill that all general thoracic surgeons need to acquire.

**OPERATIVE TECHNIQUE**

**Intraoperative Evaluation and Approaches**

At the time of the resection, bronchoscopy is used to reassess the lesion and its resectability based on the total length of
required airway resection. In cases of cervical tracheal resections, it may be possible to resect up to 5 cm of the airway. We do not recommend greater than a 4-cm resection for more distal lesions, as this may result in excessive tension on the anastomosis. For lesions approached through a right thoracotomy, mediastinoscopy can be done at the time of the resection. This serves several purposes. First, mediastinal lymph nodes can be assessed by frozen section analysis. Second, the pretracheal tissue plane can be mobilized up to the level of the cricoid cartilage, a move that facilitates tracheal mobilization. Additionally, the left recurrent laryngeal nerve can be identified and mobilized away from the left side of the trachea, which may minimize the risk of nerve injury when the trachea is approached from the right chest.

Tumors in the distal trachea, right main stem bronchus, and left main stem bronchus can be accessed through both the right chest and via the midline. The operative approaches to these tumors, therefore, are typically via a right posterolateral thoracotomy through the fourth or fifth intercostal space or through a median sternotomy. Although not contraindicated, approaching these tumors from the left chest can be challenging because of the location of the aortic arch and left pulmonary artery (LPA), both of which require mobilization to expose the carina. The left recurrent laryngeal nerve as it courses around the ligamentum arteriosum must be protected from injury and stretch during the mobilization of these structures.

Exposing the trachea through a median sternotomy requires mobilization of the ascending aorta to the patient’s left, the right pulmonary artery (RPA) caudally, and the superior vena cava (SVC) to the patient’s right. If at any time during the operation the patient becomes hypoxic, hypercarbic, or hypotensive, several physiological factors may be contributing to the clinical deterioration. Venous return may be compromised by excessive SVC retraction, cardiac output may be impeded by aortic retraction, and shunting may occur when the right lung is ventilated but the RPA is compressed resulting in a complete ventilation/perfusion mismatch. It may be necessary to adjust the retractors if hemodynamic or ventilatory compromise develops.

The initial dissection should include clearance of the subcarinal space of lymphatic tissue to facilitate exposure of the carina. Preservation of the blood supply to the lateral aspects of the main stem bronchi must be considered during this lymphadenectomy. If the lymph nodes have been previously sampled by EBUS, mediastinoscopy may not be required for cases approached with a median sternotomy. Blunt anterior dissection along the trachea, right main stem bronchus (RMB), and left main stem bronchus (LMB) is accomplished with ease through a median sternotomy. Mobilization of the membranous trachea can also be achieved with this approach, but posterior mobilization should take place after the airway has been transected. This mobilization is necessary to free the esophagus and right vagal nerve from the posterior aspect of the airway; however this dissection must be done judiciously to avoid injury and devascularization of the membranous trachea, which is perfused through small shared, esophageal branches. Preservation of the soft tissues along the lateral aspect of the trachea, RMB, and LMB is key to preserving blood supply to the surgical anastomoses; therefore blunt dissection and mobilization must be restricted to the anterior and posterior aspects of the airway (Figs. 10.2 and 10.3).

From a right thoracotomy, the division of the azygos vein can facilitate exposure to the trachea, RMB, and LMB. It is rarely necessary to retract the RPA when the approach is from the right side of the chest, therefore problems with shunt physiology during intermittent ventilation are less frequently encountered (Fig. 10.4; Table 10.2).
Release Maneuvers

The surgical tenants of preserved blood supply and minimal anastomotic tension are critical for healing of airway anastomoses. Several release maneuvers have been described as adjuncts for airway surgery including neck flexion, suprhyoid release, mobilization of the pretracheal fascia, hilar release, and division of the inferior pulmonary ligament. All of these maneuvers, with the exception of the suprhyoid release, are beneficial in the setting of a carinal resection. The last three are the most important to minimizing tension on the tracheal anastomosis. The hilar release is described as a U-shaped incision in the inferior pericardium at the level of the inferior pulmonary vein, which allows a cephalad shift of all of the hilar structures. It is important to remember to release the raphe on the lateral aspect of the inferior vena cava (IVC), which will permit further hilar movement. The pericardial incision must be placed immediately posterior to the phrenic nerve coursing along the superior pulmonary vein and around the inferior pulmonary vein. Direct cautery injury to the phrenic nerve must be avoided at all costs (Fig. 10.5).

Resection

Prior to the division of the airway, it is important to ensure that the airways have been mobilized anteriorly and posteriorly with preservation of the lateral blood supply and that the hilar release maneuvers have been completed. We identify our point of division either by palpation of the lesion or using bronchoscopic guidance. A needle can be placed through the tracheal wall and visualized bronchoscopically from the inside of the tracheal lumen to determine the optimal placement of the initial incision in the airway. Once the line of division is decided, we ensure that all equipment and team members are prepared for cross-table ventilation. Ventilation is stopped and the trachea is divided with a knife and the lesion is visualized. One must never enter an airway with electrocautery as an airway fire can result because of the high oxygen concentration. We place lateral airway traction sutures completely around a cartilaginous ring using 2-0 Vicryl or polydioxanone suture (PDS) to prevent the suture from pulling through with airway manipulation. The RMB and LMB are then divided. The specimen is removed and cross-table ventilation is initiated by placement of the reinforced ET tube into the RMB or LMB (Fig. 10.6). The specimen can be sent for frozen section analysis of

| Table 10.2 Operative Approaches to Carinal Resection |
|----------------------------------|----------------------------------|----------------------------------|
| **Right thoracotomy**            | **Median sternotomy**            | **Left thoracotomy**             |
| Access to trachea, RMB, and LMB  | Access to both right- and left-sided pulmonary parenchyma | Limited by aorta, LPA |
| Cannot access left pulmonary parenchyma or inferior pulmonary ligament | Can divide bilateral inferior pulmonary ligaments | Close proximity to recurrent laryngeal nerve |
| May require mediastinoscopy to mobilize pretracheal plane | No need for mediastinoscopy | Limited access to right-sided airway and pulmonary parenchyma |
| Requires division of azygos vein | Release retraction on RPA, if shunting occurs intraoperatively | May require mediastinoscopy to mobilize pretracheal plane |
| Can harvest intercostal muscle flap | Cannot harvest intercostal muscle flap | Cannot divide inferior pulmonary ligament on right side |
| Can harvest omentum or pericardial fat pad | | Can harvest intercostal muscle flap |

Fig. 10.4. View of trachea from right thoracotomy from surgeon’s side. “A” trachea, “B” right main stem bronchus, “C” left main stem bronchus. The azygos vein has been divided to facilitate dissection and mobilization.

Fig. 10.5. Inferior view of hilar release. A U-shaped incision is created in the pericardium around the pulmonary veins. The lateral raphe from the inferior vena cava is released. Both of these maneuvers permit additional hilar mobility to minimize the anastomotic tension. “A” IVC, “B” Phrenic nerve, “C” Pericardium-covered RV, “D” incised pericardium.
the margins or alternatively the initial resection cuts are placed very close to the tumor and three additional cartilaginous rings are removed and sent separately for margins from the trachea, RMB, and LMB (Fig. 10.7). The surgeon must always be cognizant of the importance of leaving sufficient airways intact to permit a safe reconstruction yet the attainment of a negative margin is the goal, if possible.

The patient should be physiologically stable to allow a detailed and controlled assessment of pathologic margins to determine if additional airway resection is necessary depending on histology and length of airway defect. In cases of adenoid cystic carcinoma, gross tumor resection and reconstruction of the airways are the goals of the resection. It is not uncommon for this histology to track submucosally and have microscopic positive margins. Patients with positive margins can be treated with adjuvant radiation therapy with excellent long-term survival.

Reconstruction

Once the specimen has been removed and margins have been assessed, the operative focus must shift to creating an airway anastomosis that is well vascularized and under minimal tension. The previously placed lateral traction sutures are used to position the airway and facilitate suture placement. Size mismatches and the tracheobronchial angles must be considered when creating the anastomosis. Intraoperative bronchoscopy may help to avoid the creation of tracheobronchial anastomoses with acute angles that may be difficult to appreciate from the external view. In cases of size discrepancy, the bronchial end should be allowed to intussuscept into the trachea. The anastomosis should be created with interrupted sutures of 3-0 or 4-0 Vicryl or PDS appropriately and evenly spaced. When using Vicryl sutures, we use a drop of sterile mineral oil to lubricate the suture to minimize tissue drag and potential abrasive injury to the delicate tissues, especially the membranous airway. A great deal of surgical literature emphasizes the importance of placing knots on the outside of the lumen. We have not experienced any consequences when placing knots on the inside of the lumen with these absorbable sutures. The integrity of the back wall of the anastomosis is critical because, unlike vascular structures that can be manipulated after the completion of the anastomosis, the airway becomes relatively fixed and it is difficult to rotate or visualize the sites of leaks from the back wall suture line (Fig. 10.9). For this reason we favor tying the knots on the inside of the back wall, which allows for easier suture management, better visualization of the apposition of the mucosal surfaces, and complete assurance that the knot is well seated. In cases where the anatomy is favorable, the membranous portion of the anastomosis may be sewn with a running PDS suture. The anterior wall is generally always performed with interrupted sutures with knots tied on the outside. The end result should be an airway anastomosis that is widely patent, oriented well for ventilation and secretion clearance, and under minimal tension with secure knots. The larger traction sutures are also tied at the angles to help minimize tension on the finer sutures.

In cases of carinal resection, the reconstruction options are several. The RMB and LMB can be joined to create a neocarina, which is then anastomosed to the trachea directly (Fig. 10.8). Alternatively, the RMB can be anastomosed to the trachea directly and the LMB can be anastomosed to the cartilaginous portion of the bronchus intermedius if the length permits. After completion of these anastomoses, we recommend a couple of intraoperative maneuvers to evaluate the integrity of the anastomosis including bronchoscopy and testing for pneumostasis by ventilating under saline (Figs. 10.9 and 10.10).
extubation is important to avoid positive pressure on the newly created airway anastomoses.

Aggressive pulmonary toilet with chest physiotherapy, bronchodilators, secretion clearance, and adequate pain control is essential. There should be a low threshold to use flexible bronchoscopy to facilitate pulmonary toileting in patients who are having a difficult time clearing secretions, often secondary to the transient interruption of the mucociliary clearance mechanism. We do not use routine bronchoscopy in patients who are doing well with a clear chest radiograph, but we do perform bronchoscopy prior to discharge to assess the healing of the anastomosis.

Buttress

Anastomotic integrity is of paramount importance during carinal resection as dehiscence can be fatal. We recommend soft tissue buttressing of the airway anastomoses in all cases. We use intercostal muscle flaps for cases approached from a thoracotomy but an omental tissue transfer or a pericardial fat/thymus pad when a median sternotomy is used. All of these soft tissue flaps can be harvested through the operative incision with low morbidity. The flaps should be positioned in such a way as to provide a tissue barrier between the sutures and the adjacent structures (esophagus, pulmonary artery, and aorta). When using an intercostal muscle flap it is important not to wrap the muscle 360 degrees around the airway anastomosis as anastomotic stenosis can result secondary to calcification and ossification of this particular flap which is harvested with the periosteum intact. Omental and pericardial flaps can be wrapped circumferentially around the anastomosis without concern. Pleural flaps are not used routinely as they provide minimal tissue coverage (Fig. 10.11A and 10.11B).

POSTOPERATIVE MANAGEMENT

At the conclusion of the operation we change the ET tube to a laryngeal mask airway (LMA), which permits suction bronchoscopy, a final assessment of the anastomosis and confirmation of movement of the vocal cords as the patient is awakening. Use of an LMA permits a smooth anesthetic reversal, minimal coughing, and therefore minimal pressure on the anastomosis. As mentioned earlier, postprocedure...
Postoperative complications after carinal resection include atrial dysrhythmias, atelectasis, pneumonia, respiratory failure, recurrent laryngeal nerve paresis/paralysis, anastomotic ischemia, strictureing, or partial or frank dehiscence. Nasogastric tubes can be considered in patients who have undergone a major pulmonary resection in combination with airway reconstruction, as aspiration in this setting can be fatal. However, we do not routinely use them in patients who have parenchymal-sparing airway resections and have good function of both vocal cords to protect their airway. We are conservative in initiating an oral diet until postoperative ileus has completely resolved.

If an anastomotic stricture does develop, many of these stenoses are amenable to early dilation with a rigid bronchoscope and placement of a removable silicon stent. This management is similar to that used to deal with an airway stricture following a lung transplant.

**OUTCOMES**

While carinal resections are technically demanding, excellent clinical outcomes can be achieved in high-volume centers. Thirty-day mortality rates range from 2% to 5% in most series, but can be as high as 10%. Perioperative morbidity approaches 40% in experienced centers, similar to most major general thoracic procedures. Early anastomotic complications are associated with a high mortality and must be avoided. If there is a suspicion of early anastomotic dehiscence (fever, continuous air leak, hemoptyis), bronchoscopy should be performed and there should be a low threshold for reexploration and revision of the anastomosis, if necessary.

The overall survival for patients with malignant histologies undergoing carinal resection is approximately 25% to 50% at 5 years. The need for postoperative mechanical ventilation and development of anastomotic complications are predictors of decreased overall survival on univariate analysis. Nodal status and degree of endobronchial tumor extension are predictors for decreased disease-free survival on multivariate analysis. Survival at 5 years in patients with involved mediastinal lymph nodes (N2) is 7% versus 37% for patients who are N0/N1. Locoregional control is the best option for long-term survival in patients with primary malignancies involving the carina; however, resection must be thoughtfully considered in patients with known mediastinal nodal disease since long-term survival is so poor.

**FUTURE DIRECTION**

Although carinal resection has been well established as a treatment modality for airway tumors since the 1950s, we have made slow progress to overcome the limitation of 4-cm resections for safe reconstructions. Tracheal and carinal replacement with aortic allografts may provide one method of overcoming the 4-cm barrier. The allografts, some fresh and some cryopreserved, require silicone stents to provide rigidity.

Extensive soft tissue flap coverage including pectoralis major muscle, omentum, or pericardial fat pad is necessary to prevent fistulization but no immunosuppression is required. Early results are promising in animal and human studies.

Complete tracheal replacement with a tissue-engineered nanocomposite graft has also been successfully performed in humans. The nanocomposite scaffold is seeded with autologous stem cells for 36 hours prior to implantation into the recipient. No immunosuppression is required. Early results are promising, but at the time of this writing this procedure has not been performed in the United States. This may provide an excellent alternative therapy for patients who have tumors that extend beyond the 4 to 5 cm length restrictions of present surgical techniques.

**SUMMARY**

Carinal resection is a high-risk procedure that offers acceptable clinical outcomes for patients who are appropriate candidates. Preoperatively, patient factors such as smoking and steroid cessation and optimization of physiologic and nutritional parameters help minimize perioperative morbidity and mortality. For malignant lesions, every effort must be made to exclude distant metastatic disease and the surgeon must weigh the benefit of resection in patients with regional nodal metastasis, as the long-term outcomes are quite poor. Once patient factors are optimized, technical aspects of the operation must include preservation of the lateral blood supply of the airways and utilization of release maneuvers to allow for the creation of an anastomosis under minimal tension. Immediate postoperative extubation in the operating room, aggressive pulmonary toilet, and early ambulation are crucial components to achieving a successful outcome for these patients.

**SUGGESTED READINGS**

EDITOR’S COMMENTS

As the authors correctly point out, perhaps the single most important determinant of successful outcome following carinal resection is patient selection. Resectable tumors involving the carina are extremely rare as most of the squamous carcinomas have significant extraluminal extension that precludes resection. Adenocystic carcinomas are more likely to present as resectable lesions but because of tracking along submucosal nerves the likelihood of achieving a negative resection margin is low, but with postoperative radiation therapy the long-term results remain acceptable. Mediastinal nodal involvement is associated with very poor long-term results and likely the operation should not be offered.

Whether one chooses a right thoracotomy approach or median sternotomy depends somewhat on the location of the lesion and whether or not parenchymal resection is required. Lesions involving the carina and the left main bronchus present a particular challenge since approaching the carina from the left is extremely difficult. These lesions are best approached via sternotomy with left pneumonectomy able to be carried out in addition to allowing for reconstruction with anastomosis of the right main bronchus to the distal trachea. Alternatively, a right thoracotomy allows for excellent carinal mobilization and resection but if the left lung needs to be removed a left thoracotomy would also be required.

Reconstructing the airway following carinal resection can be challenging when one lung is not removed. Because of the aortic arch there is limited mobility of the left main bronchus and depending on the length of distal trachea resected trying to reconstruct the airway by fashioning a “neocarina” can be quite difficult. The more common reconstruction involves a distal trachea to right main bronchus anastomosis with the left main bronchus attached to the lateral cartilaginous portion of the right main bronchus. An anastomosis that is under minimal tension is critical for success. Anastomotic dehiscence is a disastrous complication and commonly results in mortality. If there is any question in the early postoperative course regarding anastomotic integrity, a bronchoscopy needs to be performed and potentially reoperation with repair of the anastomosis. Aggressive secretion management in the postoperative period is also critically important. Bottom line: these are high-risk, technically challenging surgical procedures with a high likelihood of major morbidity. It probably is safe to say that carinal resections should be limited to those centers that have significant experience in dealing with surgery of the airway.

LRK
INTRODUCTION

Video-assisted thoracic surgery (VATS), also termed thoracoscopy, refers to minimally invasive chest surgery that avoids rib spreading and rib resection and relies entirely on cameras and video technology for visualization. Thoracoscopic techniques may be applied to a variety of thoracic procedures, but thoracoscopic pulmonary resections are the most commonly performed. Despite the potential advantages of minimally invasive surgery, only approximately 30% of major pulmonary resections are currently completed using the thoracoscopic technique. The strategies and outcomes of thoracoscopic pulmonary resections are described, with a focus on anatomic procedures.

BASIC PRINCIPLES

Single-lung ventilation is required and may be achieved with a dual-lumen endotracheal tube or a bronchial blocker. The patient is placed in the lateral decubitus position. It is helpful to limit the tidal volume to increase the space within the thorax, and pressure-controlled ventilation is preferred. Most thoracoscopic anatomic resections may be performed via two or three incisions, and the overwhelming majority in our experience has been performed with only two incisions. Wedge resections should require no more than two incisions. The placement of port incisions vary according to the preference and experience of the surgeon. In general, the port positions are the same whether an upper, lower, or middle lobectomy is performed, as this strategy places the access incision over the major fissure. The first port, placed in the 7th intercostal space in the midaxillary line, is used predominantly for camera placement and, ultimately, chest tube placement. The second incision (4 to 6 cm) is placed in the 5th or 6th intercostal space in the anterior axillary line. This site is chosen, in part, to allow easy access to hilar structures and to allow for extraction of the specimen (Fig. 11.1).

WEDGE RESECTIONS

Thoracoscopic wedge resections may be performed for various indications, both diagnostic and therapeutic. In general, wedge resections are technically straightforward, and the most difficult aspect of the procedure may be the localization of the nodule to be resected. Localization may
bifurcation, which will facilitate bronchial dissection later from the anterior approach. The lung is then reflected posterior to allow dissection of the superior pulmonary vein. Although uncommon, the presence of a common pulmonary vein must be excluded. Dissection is performed to identify the bifurcation of the upper and middle lobe veins. Once the upper lobe vein has been clearly identified, it is circumferentially dissected free and divided with a vascular stapler. This reveals the underlying pulmonary artery. In a similar fashion, the pulmonary arteries to the upper lobe are mobilized and divided, beginning with the truncus anterior. The last structure to be dissected is usually the bronchus; however, occasionally the bronchus is divided prior to dissection of the posterior ascending artery. After dividing the bronchus, the fissures are developed and divided using stapling devices and the specimen is extracted from the chest in a protective bag.

**Left Upper Lobectomy**

Thoracoscopic left upper lobectomy is performed in a similar fashion to that on the right. Posterior dissection is undertaken first to divide the pleural reflection and to expose the left pulmonary artery as it emerges under the aorta and to identify the posterior artery; as with the right upper lobe, this posterior dissection will greatly facilitate the completion of the hilar dissection from the anterior approach. With the lung retracted posteriorly, dissection is used to identify both pulmonary veins (to ascertain that a common pulmonary vein is not present). The superior pulmonary vein is then encircled and divided, revealing the underlying pulmonary artery and upper lobe bronchus. Dissection of the lymph nodes between the cephalad aspect of the bronchus and the arterial trunk (to the anterior and apical segments) will facilitate the ultimate arterial dissection. The branches of the arterial trunk can now be individually exposed and divided, followed by division of the posterior branch. Bronchial dissection and division is now easily accomplished, followed by division of the lingular arteries. Finally, the major fissure is divided with the stapling device, and the lobe is removed in a protective specimen bag.

**Left and Right Lower Lobectomy**

There are two basic strategies for lower lobectomy, both of which begin with division of the inferior pulmonary ligament, followed by dissection and division of the inferior pulmonary vein. The preferred method does not involve dissection within the fissure (which is stapled last, as with upper lobectomy). After dividing the vein, attention is directed to the bronchus by retracting the lobe cranially, a perspective not obtained via thoracotomy. A plane is created between the bronchus and the artery by dissecting close to the bronchus, which is then divided. For right lower lobectomy, this dissection is begun at the bifurcation with the middle lobe bronchus, which must be preserved. For left lower lobectomy, the dissection is undertaken at the bronchial bifurcation, after identifying the lingular bronchus. After division of the bronchus, the arterial trunk is then encircled and divided, although it is sometimes easier to divide the branches to the superior and basilar segments individually. Ultimately, the fissure is divided and the specimen removed in a protective specimen bag.

The alternative method involves opening the fissure, and stapling the lower lobe pulmonary arterial trunk, followed by stapling of the bronchus. If this method is employed, there may be an advantage to stapling the fissure after careful dissection in the arterial plane, as opposed to dissecting the fissure bluntly, which is often done in open procedures.

**Middle Lobectomy**

Unlike other lobectomy procedures, the strategy for middle lobectomy begins with opening the major fissure. This is not performed to expose the pulmonary vessels; rather, it allows passage of the stapler to ligate the middle lobe pulmonary vein. The bronchus is then dissected and stapled, with identification and preservation of the bronchus intermedius. The middle lobe pulmonary artery is then stapled. Finally, the horizontal fissure is stapled and the lobe is removed in a protective specimen bag.

**OUTCOMES WITH THORACOSCOPIC LOBECTOMY**

Recently, single-and multiinstitutional studies have demonstrated that thoracoscopic lobectomy is an accepted oncologic procedure for patients with early stage lung cancer, and is recommended in treatment guidelines for nonsmall-cell lung cancer (NSCLC). Thoracoscopic lobectomy has been demonstrated to have better outcomes compared to conventional thoracotomy.
including shorter length of stay, shorter chest tube duration, decreased postoperative pain, improved preservation of pulmonary function, reduced inflammatory response, shorter recovery time, lower cost, and better compliance with adjuvant chemotherapy when required. In addition, it has been demonstrated that thoracoscopic lobectomy is a safer procedure than lobectomy by thoracotomy, as it is associated with fewer postoperative complications.

Using a prospective database, the outcomes of patients who underwent lobectomy at Duke from 1999 to 2009 were analyzed with respect to postoperative complications. Propensity-matched groups were analyzed based on preoperative variables and stage. Of the 1,079 patients in the study, 697 underwent thoracoscopic lobectomy and 382 underwent lobectomy by thoracotomy. In the overall analysis, thoracoscopic lobectomy was associated with a lower incidence of prolonged air leak (P = 0.0004), atrial fibrillation (P = 0.01), atelectasis (P = 0.0001), transfusion (P = 0.0001), pneumonia (P = 0.001), sepsis (P = 0.008), renal failure (P = 0.003), and death (P = 0.003). In the propensity-matched analysis based on preoperative variables, comparing 284 patients in each group, 196 patients (69%) who underwent thoracoscopic lobectomy had no complications, versus 144 patients (51%) who underwent thoracotomy (P = 0.0001). In addition, thoracoscopic lobectomy was associated with fewer prolonged air leaks (13% vs. 19%; P = 0.05), a lower incidence of atrial fibrillation (13% vs. 21%; P = 0.01), less atelectasis (5% vs. 12%; P = 0.006), fewer transfusions (4% vs. 13%; P = 0.002), less pneumonia (5% vs. 10%; P = 0.05), less renal failure (1.4% vs. 5%; P = 0.02), shorter chest tube duration (median 3 vs. 4 days; P < 0.0001), and shorter length of hospital stay (median 4 vs. 5 days; P < 0.0001). Simultaneous results were obtained when the Society of Thoracic Surgeons (STS) database was analyzed by Paul and colleagues. All patients undergoing lobectomy as the primary procedure via thoracotomy or thoracoscopic lobectomy were identified in the STS database from 2002 to 2007. After exclusions, 6,232 patients were identified: 5,042 thoracotomy and 1,281 thoracoscopic. A propensity analysis was performed, incorporating preoperative variables, and the incidence of postoperative complications was compared. Matching based on propensity scores produced 1,281 patients in each group for analysis of postoperative outcomes. After VATS lobectomy, 945 patients (73.8%) had no complications, compared to 847 patients (65.3%) who had lobectomy via thoracotomy (P < 0.0001). Compared to open lobectomy, VATS lobectomy was associated with a lower incidence of arrhythmias (N = 93 [7.3%] vs. 147 [11.5%]; P = 0.0004), reintubation (N = 18 [1.4%] vs. 40 [3.1%]; P = 0.0046), and blood transfusion (N = 31 [2.4%] vs. N = 60 [4.7%]; P = 0.0028), as well as a shorter length of stay (4.0 vs. 6.0 days; P < 0.0001) and chest tube duration (3.0 vs. 4.0 days; P < 0.0001). There was no difference in operative mortality between the two groups.

Finally, Berry and colleagues reported a recent analysis of high-risk patients over 70 years of age. During the study period, 338 patients older than 70 years (mean age 75.7 ± 0.6) underwent lobectomy (219 thoracoscopy, 119 thoracotomy). Operative mortality was 3.8% (13 patients) and morbidity was 47% (159 patients). Patients with at least one complication had increased length of stay (8.3 ± 0.6 vs. 3.8 ± 0.1 days; P < 0.0001) and mortality (6.9% [11 of 159] vs. 1.1% [2 of 179]; P = 0.008). Significant predictors of morbidity by multivariable analysis included age (odds ratio 1.09; P = 0.01) and thoracotomy as surgical approach (odds ratio 2.21; P = 0.004). Thoracotomy remained a significant predictor of morbidity when the propensity to undergo thoracoscopy was considered (odds ratio 4.9; P = 0.002).

### SEGMENTECTOMY

As experience with thoracoscopic lobectomy increases, minimally invasive strategies are being more readily applied to more complex cases and surgical interventions, including segmentectomy. A recent review of the STS database demonstrates that segmentectomy is performed in approximately 5% of pulmonary resections at institutions contributing to the database. Thoracoscopic segmentectomy is defined as a sublobar resection of one or more anatomic pulmonary segments using a completely minimally invasive approach. As with thoracoscopic lobectomy, visualization is dependent on video monitors and rib spreading is avoided. Thoracoscopic segmentectomy employs anatomic resection, with individual vessel ligation. Hilary and mediastinal lymph node dissection are a standard part of the procedure.

#### Technique for Thoracoscopic Segmentectomy

**Lingula-Sparing Left Upper Lobectomy (S1–3)**

This segmentectomy is performed by dividing the pleural reflection posteriorly, beginning over the left pulmonary artery near the fissure and extending the pleural division cranially to the aortopulmonary window. Attention is then turned anteriorly, pleural dissection is continued to complete the circumferential pleural division of the hilum. The upper lobe proper branches of the left superior pulmonary vein are then encircled and divided with a linear stapler, sparing the lingular vein. This maneuver (and all stapling for this segment) is facilitated by moving the camera to the anterior...
access incision so that the stapler may be introduced through the “camera” incision.

Reflection of the distal stapled vein allows identification of the apical-posterior arterial and bronchial segmental branches to the upper division. The space between the arterial branches and the upper lobe bronchus is developed, providing exposure for stapling the anterior and apical branches of the left upper lobe artery. The previous posterior dissection greatly facilitates this maneuver. Dissection of the left upper lobe bronchus is then initiated at the bifurcation with the lingular branch, where there is often a small lymph node. The bifurcation of the lingular bronchus is usually behind the intact lingular vein, but care must be taken that the entire left upper lobe bronchus is not dissected.

Once the bronchus is divided, an anterior segmental arterial branch within the fissure will be unveiled. This arterial branch can be dissected and stapled. Parenchymal division with the stapler completes the segmentectomy. This is facilitated by grasping the stapled bronchial stump to provide retraction of the upper division away from the hilum. In some patients, a visible segmental fissure or demarcation is present; however, hilar anatomic landmarks are always present to identify the correct line of division. When the segmental anatomy is not clear, temporary re-inflation of the lingula distinguishes the atelectatic upper division for parenchymal resection.

**Lingulectomy (S4–5)**

Unlike most lobar and sublobar thoracoscopic resections, lingular segmentectomy is initiated by opening the oblique fissure, as with middle lobectomy. Once the fissure is open, the upper lobe is retracted posteriorly, exposing the lingular vein. The vein is encircled and divided with a stapler, exposing the bifurcation of the upper lobe division and lingular bronchi. The lingular bronchus is encircled and stapled, exposing the lingular arterial branches, which are then stapled and divided as well. The segmentectomy is completed with parenchymal division. As with other thoracoscopic anatomic resections, this is facilitated by grasping the stapled bronchial stump to provide retraction of the lingula away from the hilum. In some patients, a visible segmental fissure or demarcation is present; however, hilar anatomic landmarks are always present to identify the correct line of division. When the segmental anatomy is not clear, temporary re-inflation of the upper division distinguishes the atelectatic lingula for parenchymal resection.

**Superior Segmentectomy (S6)**

As with most anatomic thoracoscopic resections, division of the pleura posterior facilitates the procedure. The inferior pulmonary ligament is divided with electrocautery to the level of the inferior pulmonary vein, and the division of the posterior pleural reflection is continued cranially to the pulmonary artery. The inferior pulmonary vein is then identified and dissection on its posterior surface undertaken to expose the superior segmental vein. Once the vein is encircled and stapled, the superior segmental bronchus is exposed; there is often a small lymph node at this bifurcation, which should be removed for oncologic purposes as well as to improve exposure. The segmental bronchus is then divided, which exposes the segmental artery. The artery may at that point be stapled; alternatively, the segmental artery may be approached by opening the posterior aspect of the oblique fissure. The segmentectomy is completed by dividing the parenchyma with the stapler.

**Basilar Segmentectomy (S7–10)**

As with superior segmentectomy (S6), basilar segmentectomy is initiated with division of the inferior pulmonary ligament and the posterior pleural reflection to expose the inferior pulmonary vein, including the bifurcation of the superior segmental and basilar segmental veins. Anterior dissection is then undertaken to encircle the basilar segmental veins, which may be stapled. Superior retraction of the lung exposes the lower lobe bronchus, and the basilar segmental bronchi may then be dissected using this approach. Once again, thorough posterior dissection, in this case between the bronchus and the artery, greatly facilitates this strategy. Once the basilar segmental bronchi are stapled, the basilar segmental arteries are similarly divided, followed by division of the anterior portion of the major fissure. Finally, the parenchymal resection is performed.

Alternatively, after division of the basilar segmental veins, the anterior portion of oblique fissure may be opened to expose the basilar segmental arteries. Division of the arteries exposes the bronchi, which are similarly stapled and divided, sparing the superior segmental vessels. The parenchymal resection is then completed with the stapler.

**Posterior Segment of the Right Upper Lobe (S–2)**

Although posterior segmentectomy is an uncommon procedure for NSCLC, as retention of the apical and anterior segments is less likely to result in preserved pulmonary function, this procedure may be beneficial in patients with relatively central pulmonary metastases. In these patients, large wedge resections may compromise more pulmonary parenchyma than a precise segmentectomy. Dissection is once again begun posteriorly, to divide the pleural reflection, to expose the posterior aspect of the right upper lobe bronchus, and to begin to open the posterior portion of the oblique fissure. At this point, identification and division of the posterior ascending artery may be performed. Further dissection within the fissure exposes the posterior segmental vein as it courses underneath the horizontal and oblique fissures. Once the vein is divided, the parenchyma of the posterior segment is reflected off of the interlobar pulmonary artery, providing visualization of the anterior trunk and the bifurcation of the posterior segmental bronchi, which is then stapled. There is often a substantial lymph node or nodes in this location, and complete dissection should be performed. The parenchymal division is then performed with the stapler.

**PNEUMONECTOMY**

Experience with thoracoscopic pneumonectomy is limited, and the advantages conferred on minimally invasive strategies for lobectomy and segmentectomy may not be necessarily conferred on pneumonectomy. Nevertheless, it is reasonable to pursue investigation of this technique, including feasibility, safety, and outcomes. In a recent review, the outcomes of 67 patients who underwent pneumonectomy for malignancy were analyzed, including 32 patients in whom thoracoscopic pneumonectomy was attempted. Patients in the thoracoscopic group had shorter lengths of stay in the hospital and less operative blood loss; however, the 8 patients who were converted to thoracotomy had significantly more operative blood loss. The complication rates were similar among thoracoscopic, converted, and open groups. While this study does demonstrate safety and feasibility, further studies are required to determine outcome advantages.

**AWAKE THORACOSCOPIC SURGERY**

Despite the notable advantages of VATS over thoracotomy for pulmonary resections, use of general anesthesia, which is still considered mandatory for VATS, can be associated
Awake Pulmonary Metastasectomy

Since the majority of pulmonary metastases are located peripherally, VATS has been advocated as a viable option particularly in patients with solitary lesions. As discussed above, potential advantages of VATS over open approaches include less pain, lower morbidity rate, and shorter hospital stay. Recently, awake VATS metastasectomy through TEA has been proposed in order to minimize surgical stress. In a cohort of 14 patients undergoing awake VATS metastasectomy, the procedure was demonstrated to be feasible and safe, accomplished under TEA in all patients with no operative mortality or major morbidity. Hospital stay was significantly shorter than in a control group operated through general anesthesia while intermediate-term results and survival were similar.

Awake Resection of Indeterminate Pulmonary Nodules

Awake VATS, performed with thoracic epidural anesthesia (TEA) and sedation, has been successfully applied for removal of indeterminate pulmonary nodules. The indication is the need to obtain a rapid, histologically proven diagnosis of nodule in patients in whom further surgical resection is not indicated. Eligibility criteria include radiologic findings of a nodule less than 3 cm in maximal size at CT and localized in the peripheral one-third of the lung. The presence of anxiety, which interferes with full patient cooperation in the operating room, is considered a potential contraindication, but this can be controlled in most instances by sedation.

In a small randomized comparison of VATS wedge resection performed with TEA or with general anesthesia plus TEA, technical feasibility was equivalent in the study groups, whereas the perioperative stress hormone response and better preserved lymphocyte activity, which might also improve outcomes.

Awake Resection of Lung Cancer

Resection of lung cancer represents the most provocative indication for awake VATS, and to date both lobectomies and pneumonectomies have been performed through TEA in fully awake patients. Proposed inclusion criteria for awake resection of lung cancer include peripheral stage I lesions, age older than 75 years, poor pulmonary function, or other comorbidities leading to consider the patient at high risk for anatomic resection or for general anesthesia. In addition, selected patients with peripheral lesions previously considered medically inoperable, who already underwent percutaneous radiofrequency ablation or stereotactic radiofrequency ablation, can be eligible for an awake lung resection.

ROBOTIC-ASSISTED THORACIC SURGERY

Abbas E. Abbas

As noted in this chapter the advent of endoscopic VATS, allowed for the performance of anatomic lobectomies with complete mediastinal lymph node dissection through small ports instead of a large thoracotomy and has become the goal of many thoracic surgeons. As noted by Dr. Pompeo and Dr. D’Amico, the technique has been shown to have equal or even better outcomes compared to open thoracotomy when performed by surgeons facile and experienced in this technique. However, many factors have made the adoption of VATS lobectomy less than universal as currently less than one-third of anatomic pulmonary resections are accomplished with a VATS approach. These factors include the inadequacy of precise dissection of the vascular and mediastinal structures within the thoracic cavity due to the limited maneuverability of the instruments and limitations of the two-dimensional view of the operative field. In addition, there is the concern for the loss of immediate control of the pulmonary hilum in case of bleeding. For most surgeons mastering VATS lobectomy is also associated with a prolonged learning curve. Robotic-assisted thoracic surgery (RATS) may offer an alternative to address some of these concerns. Robotic instruments are wristed and have 360 degrees of freedom, mimicking maneuvers done with the human wrist during open surgery. The image seen by the surgeon is high definition and three-dimensional with 10 times optical zooming and is a significant improvement over that available with VATS. This makes RATS quite ideal for fine dissection in a confined space such as the pleural cavity. However, there are also certain concerns associated with RATS. There is a lack of tactile feedback that must be compensated for by visual cues. In addition, the concern for loss of control may be greater with VATS, as the surgeon is not even at the field while performing the procedure. It is therefore important to have an experienced surgical team at the table that is adept at dealing with different scenarios in the execution of this operation, including emergency conversion to thoracotomy for bleeding.

The procedures described for robotic lung surgery have included “hybrid” techniques with robotic assistance to open or thoracoscopic surgery. Examples of these techniques are those where the robot is used during the dissection phase of the lobectomy, including dissection of the mediastinal, hilar, and subcarinal structures. For the subsequent vascular, parenchymal, and bronchial division along with removal of the specimen from the chest cavity, standard VATS lobectomy techniques were used with the robot undocked and the surgeon scrubbed into the surgical field. More recently, the totally endoscopic and completely portal (TECP) approach has become the standard technique for most surgeons who practice robotic thoracic surgery. This technique mimics the exposure and approach of a thoracotomy, as most of the ports for the camera and robotic arms are along the same intercostal space (ICS). It can be performed with either three or four arms depending on surgeon preference.

Our own approach to lobectomy is a totally endoscopic four-arm technique using the da Vinci Surgical System (Intuitive Surgical, Inc. Sunnyvale, CA). After induction of general anesthesia, intubation, and bronchoscopy, a bronchial blocker or double-lumen tube is inserted. The patient is then placed in the lateral decubitus position and the bed is flexed at the level of the 7th ICS (Fig. 11.2). The robot is then brought in directly over the head of the patient.

Five ports are then inserted. The first is a 12 mm port at the 9th ICS for CO2 insufflation and assistance. Another four ports are placed ranging from 5 to 8.5 mm, attempting to place all in one ICS, usually the 7th or 8th ICS depending on the patient’s body habitus (Fig. 11.4). These ports are placed with guidance from a thoracoscope placed through the assistant port and will be at or close to the midclavicular line, anterior axillary line, posterior axillary line, and paraspinall. In general, the ports should be placed about a hand’s breadth or 9 to 10 cm apart to avoid external collision between the arms. The robot is then brought in from the head.
of the table and the surgeon moves to the console (Fig. 11.3).

Arm #3 is used mainly for retraction using a 5-mm lung-grasping instrument and is placed posterolateral to either the left or the right arm depending on the side of the lobectomy. The remaining two arms are both 8 mm and are used for the majority of the dissection. For right-handed surgeons, the left arm usually uses a Cadiere forceps for gentle traction, whereas the right arm uses an instrument with an energy source such as the Maryland forceps with bipolar cautery. A left-handed surgeon can simply reverse the instruments. A variety of other instruments including a monopolar hook cautery, monopolar scissors, and a wristed suction dissector are also available.

Dissection is begun by dividing the inferior pulmonary ligament and incising the mediastinal pleura circumferentially around the hilum. In the process, a complete mediastinal lymph node dissection is performed. Following this, the approach to lobectomy is the same as that for the open procedure. After dissection and removal of the specific N1 nodes, sequential division of the pulmonary vein, pulmonary arterial branches, bronchus, and fissure is undertaken. The order is sometimes changed to accommodate for individual anatomic variations. The lobe is finally completely detached and placed in a surgical pouch for removal from the assistant port after converting it to a 3 to 5 cm subcostal incision through the diaphragm and below the 10th rib as has previously been described by Dylewski et al. Others have described creating a minithoracotomy utility incision for extraction of the lobe.

**SUMMARY**

Minimally invasive pulmonary resection has become an accepted, safe, and oncologically sound procedure. A number of studies have demonstrated that the use of thoracoscopic lobectomy is associated with less postoperative pain, reduced length of stay, better compliance with adjuvant therapy, and fewer postoperative complications. Although the thoracoscopic strategy may be difficult to learn, it is increasingly becoming the preferred method of anatomic lobectomy. RATS may address a number of the limitations presented by VATS lobectomy. The ability to have “wristed” instruments with 360 degrees of freedom allows one to essentially recreate an open operation within the confines of the closed chest. All of the port incisions for docking the robot occur along a single intercostal space as in an open thoracotomy. The three-dimensional visualization with magnification allows for precise dissection of bronchovascular structures and new and improved instruments are continually being introduced. These include the recently developed linear staplers for use with the robotic arms. In light of the outcome of the National Lung Screening Trial, the use of thoracoscopic or robotic procedures is certain to increase. In the future, minimally invasive strategies will be more commonly used in the management of locally advanced lung cancer, including patients with chest wall tumors, patients...
after induction therapy, and patients that require pneumonectomy.

SUGGESTED READINGS

Pompeo E, Mineo TC. Two-year improvement in multidimensional body mass index, airflow...

This is a critically important chapter in that it represents the state of the art in minimally invasive thoracic surgery, specifically pulmonary resection. Dr. D’Amico has been at the forefront of the development of VATS lobectomy and is one of the most experienced practitioners of the procedure. It must be stressed that the learning curve is prolonged and newly minted surgeons would be well advised to be intimately familiar with open surgical techniques prior to embarking on complex resections utilizing a VATS approach.

Response to significant intraoperative hemorrhage remains one of my major concerns with any minimally invasive approach. Though it happens only infrequently, bleeding from a pulmonary arterial branch does occur during the performance of a pulmonary resection. When the chest is open often just digital pressure suffices to staunch the bleeding, but if the hemorrhage is significant it is fairly straightforward to obtain proximal control of the main pulmonary artery if it had not already been done as part of the routine. The authors point out that pressure on the bleeding area with a sponge stick usually suffices to control bleeding but with limited visualization and the inability to put a hand in the chest complete control may be difficult to achieve. Sufficient control of significant bleeding must be accomplished to allow time to open the chest in at least some of the situations that may be encountered. In addition, repairing a rent in the pulmonary artery is best and most safely accomplished when there is proximal control of bleeding. Blindly trying to put a stitch in a bleeding pulmonary artery usually results in further disaster. Though no surgeon likes to talk about it, there have been intraoperative deaths resulting from massive hemorrhage during VATS lobectomy that never would have had a fatal outcome if the procedure had been done open. This is not to say that VATS is any more dangerous, only that a contingency plan for a disaster should be well thought out.

The authors have nicely described the technique for the various anatomic resections noting that dividing the vein first facilitates the rest of the procedure. I differ with their description of middle lobectomy in that it is not necessary, or recommended, to dissect in the fissure to identify the artery. Middle lobectomy may be expeditiously accomplished by identifying and dividing the middle lobe vein at the hilum as the initial maneuver. Following division of the middle lobe vein, the middle lobe bronchus is easily visualized and can be divided nicely revealing the middle lobe artery or arteries. Once the arterial branch or branches are divided the minor fissure and oblique fissure may be taken with a linear stapler to complete the resection. The same approach may be employed for a lingular segmentectomy again avoiding the messy dissection within the fissure.

Having for a long time been a nonbeliever I have become a convert to the use of the robot for pulmonary resection and, in fact, feel that it is a better operation than the VATS procedure. This occurred once I observed an experienced robotic surgeon in action and saw some of the currently available instruments. The introduction of the robotic linear staplers will be a major advance that I believe will, and should, convert more surgeons to a robotic approach. It truly is “intuitive” and really is an extension of the open procedure yet done within the confines of the chest. Abbas nicely describes his technique and elaborates specifically how he removes the lobe from the chest. The use of the robotic arms avoids the levering that occurs between the thoracoscopic instruments and the rib edges during VATS procedures likely further attenuating postoperative pain. Some would argue that the additional expense incurred by a robotic procedure outweighs the potential advantage over the VATS approach but in hospitals where multiple specialties are using the robot, the expense is diffused somewhat by being spread across multiple users. Whether VATS or robotics, the decision must be based on the experience and comfort of the surgeon. Both techniques appear to be a benefit to the end-user, the patient, and that really is what matters most.

Management of Pneumothorax and Bullous Disease

Stephen D. Cassivi and Claude Deschamps

The pleural space is a potential space during normal conditions with the visceral pleura directly in apposition to the parietal pleura. Pneumothorax is defined as the presence of air in the pleural space and can be due to a number of causes. The etiology and volume of the pneumothorax and the resultant intrapleural pressure and condition of the underlying lung play a role in determining the clinical severity.

This chapter outlines the anatomy and basic physiology of the pleural space. The pathophysiology of the various etiologies of pneumothoraces is discussed, as are the diagnosis and management options. Special attention is directed to the particular condition of bullous disease.

ANATOMY

The pleural space is lined by the visceral and parietal pleurae (Fig. 12.1). The visceral pleura is a thin layer (usually one cell thick) intimately covering the outer surface of the lung. It adheres to the underlying alveolar walls of the lung parenchyma via connective tissue made up of elastic fibers. There is, therefore, no true cleavage plane between the visceral pleura and the lung parenchyma that it envelops. The visceral pleura has no somatic innervation.

The parietal pleura is a more complex serous membrane. It lines the inside of the chest wall, the diaphragm, and the mediastinum and is attached to these by a fibrous and connective tissue layer known as the endothoracic fascia. Between the endothoracic fascia and the parietal pleura is a dissection plane that allows the parietal pleura to be stripped off of the chest wall and other structures. It is thickest and most substantial along the chest wall, overlying the ribs, and thinnest as it covers the mediastinal structures and beneath the sternum. The parietal pleura is innervated by somatic, sympathetic, and parasympathetic nerve fibers via the intercostal nerves.

PHYSIOLOGY

The physiology of the pleural space is relatively straightforward, although dynamic. Functional residual capacity is the measure of lung volume with the patient at rest after normal exhalation. In this state, the elastic and retractive nature of the chest wall and lung pull the parietal and visceral pleurae away from one another, thus creating a negative intrapleural pressure usually in the range of −2 to −5 cm H₂O. During inspiration, the outward chest wall and diaphragmatic forces counteracting the normal elastic recoil of the lung parenchyma can create intrapleural pressures of −20 to −35 cm H₂O. Gravity also exerts an influence on this negative intrapleural pressure. In the upright position, the apex has a greater negative intrapleural pressure than the base of the lung in the region of the costophrenic sulci (0.25 cm H₂O/cm of height). This phenomenon may contribute to some degree to creating increased distention of alveoli in the apex and a greater predisposition to spontaneous pneumothoraces by rupture of apical blebs.

As a consequence of having more oxygen consumed than carbon dioxide produced during the respiratory cycle (respiratory quotient <1), there is a resultant partial pressure gradient between the gases in the venous blood and those of the arterial system and pleural space. This gradient, usually between 54 and 72 cm H₂O, ensures against spontaneous gas formation in the pleural space as long as the intrapleural pressures do not become less than −72 cm H₂O. On a more practical level, this also explains how intrapleural air, as in the case of a pneumothorax, can be gradually reabsorbed by diffusion into the venous circulation.

Pleural gases can also be affected by barometric pressure. Whereas the relative proportions of gases do not change with variation in atmospheric pressure, there can be a significant change in the volume of these gases. Boyle’s law states that at constant temperature, for a given mass of gas, pressure $p$ multiplied by volume $V$ is a constant:

$$pV = c$$

Thus, the volume change in a gas is inversely proportional to the change in atmospheric pressure. This has a number of clinically significant consequences when considering pneumothoraces. First, although a person with a pneumothorax being transported by airplane is likely to be in a pressurized cabin, one can expect the barometric pressure to decrease, with a resultant proportional increase in the volume of their pneumothorax if there is not a path of egress for the intrapleural gas such as provided by a chest tube. Second, a clinician whose practice is located at a higher altitude (with lower atmospheric pressure) can expect a slower resolution of pneumothoraces by resorptive diffusion alone than that seen by a colleague practicing closer to sea level.

ETIOLOGY AND PATHOPHYSIOLOGY

Primary spontaneous pneumothorax is the most common cause of pneumothoraces and has an estimated overall incidence of 5 to 10 cases per 100,000 per year. It occurs predominantly in young, healthy men, with an incidence in this group as high as 1 in 500 per year, and is due in most cases to rupture of apical subpleural blebs in otherwise normal lungs (Fig. 12.2). The pathogenesis of these apical blebs is unclear, although it is postulated that higher transpulmonary pressures at the apex lead to greater alveolar distending pressures. The resultant rupture of alveoli traps air between the internal and external elastic membranes of the visceral pleura. It is noted that these types of pneumothoraces most often occur in tall, thin individuals, many of whom are smokers. The lifetime risk of developing a pneumothorax in an otherwise healthy man is estimated at 0.1%, whereas it is as high as 12% in one who is a smoker. There may also be an association with connective
Chapter 12: Management of Pneumothorax and Bullous Disease

Spontaneous pneumothorax can also occur as a result of underlying lung disease, in which case it is referred to as a secondary spontaneous pneumothorax. There are various pulmonary disease states leading to secondary pneumothoraces (Table 12.1). Most cases are related to bullous-type disease, with hyperinflation leading ultimately to rupture and subsequent pulmonary parenchymal collapse. Diseases characterized by cystic lesions in the pulmonary parenchyma such as cystic fibrosis and lymphangioleiomyomatosis can also lead to spontaneous rupture and pneumothorax. Malignant tissue disorders such as Marfan syndrome. A familial form of spontaneous pneumothorax has been described with autosomal-dominant inheritance and incomplete penetrance.

**Traumatic**
- Blunt
- Penetrating
- Barotrauma

**Barotrauma**
- Ventilator induced

Whether deliberate or accidental, may result in a so-called acquired pneumothorax. This is usually due to a breach or laceration of the visceral pleura. This can occur during procedures such as transthoracic needle aspiration, central line placement in the neck, and thoracentesis. In the latter procedure, recent studies have shown that the incidence of iatrogenic pneumothorax can be significantly reduced by using ultrasound guidance.

**Fig. 12.3.** Diaphragmatic surface demonstrating a probe passing through a transdiaphragmatic fenestration.

The most common presenting symptom of spontaneous pneumothorax is ipsilateral pleuritic chest pain of relatively sudden onset. Dyspnea may or may not be a prominent symptom and is usually proportional to the amount of lung collapse. Ipsilateral decreased breath sounds and hyperresonance on percussion are usually noted. In the case of a tension pneumothorax, there may also be deviation of the trachea to the contralateral side, tachycardia, hypotension, and diaphoresis. Although they are useful in suggesting the diagnosis of pneumothorax, clinical history and physical examination are not generally reliable in predicting the volume of underlying lung collapse.

Standard posteroanterior (PA) chest radiographs (CXR) remain the standard for the diagnosis of spontaneous pneumothorax in the clinically stable
patient. If the diagnosis is suspected but is not confirmed by a standard upright CXR taken on inspiration, a CXR taken either during expiration or in the lateral decubitus position may accentuate the pneumothorax and facilitate diagnosis. Computed tomography (CT) scans are the most sensitive and specific imaging modality for the diagnosis of pneumothoraces and can be especially useful in differentiating such a diagnosis from that of a large emphysematous bullae.

A large body of literature exists positing many methods of estimating the volume of the pneumothorax as a percentage of the pleural space volume. None of the methods has been universally accepted. CT scans are much more precise for such estimates because they take into account the nonuniform collapse that usually characterizes spontaneous pneumothoraces. However, the clinical usefulness of a precise measurement of pneumothorax size is debatable. Most often treatment decisions are made on the basis of a relative estimate of pneumothorax size, its evolution over time, and, more important, the clinical status of the patient.

**TREATMENT**

The most important factor to consider in the management of a patient with a pneumothorax is the clinical status. An unstable patient, whether due to the hemodynamic compromise resulting from a tension pneumothorax or the respiratory compromise of a clinically significant simple pneumothorax, requires urgent treatment. This can be accomplished, in the case of a tension pneumothorax, by immediate insertion of a 14-gauge angiocatheter in the ipsilateral mid-clavicular line in the second interspace. This is followed by an expeditious insertion of an ipsilateral chest tube to evacuate the remaining air and reexpand the underlying lung.

There are a number of treatment options for patients with pneumothoraces, either primary or secondary (Table 12.2). In the clinically stable patient with a spontaneous pneumothorax, an evaluation should first be made of his or her level of dyspnea or breathlessness as well as the relative size of the pneumothorax (Fig. 12.4). In a patient with little or no breathing difficulties and a small pneumothorax (<20%), it is reasonable to observe the patient with a repeat CXR in approximately 6 hours. If the pneumothorax has not progressed and the patient has not developed worsening symptoms, further observation as an outpatient with return in 24 to 48 hours for reassessment by clinical exam and repeat CXR usually is all that is necessary.

The rate of resolution of a spontaneous pneumothorax by reabsorption is between 1.25% and 1.8% per day. Using high concentrations of oxygen in the inspired gas in an effort to create a gradient of nitrogen favoring reabsorption of intrapleural gas has been shown to increase the resolution of pneumothoraces by up to four times the rate on room air. However, hospitalization for the sole purpose of providing high-flow oxygen in an effort to hasten the resolution of the pneumothorax is likely unnecessary and is not advocated.

![Fig. 12.4. Algorithm for the treatment of spontaneous pneumothoraces (CXR, chest X-ray).](image-url)
In patients with few respiratory symptoms and moderate-to-large pneumothorax, there is growing evidence that a trial of needle aspiration may be warranted. The consensus guidelines from both the American College of Chest Physicians and the British Thoracic Society advocate an initial trial of needle aspiration in these cases. These recommendations are based on studies showing initial aspiration to be as effective as chest tube management in resolving pneumothoraces in patients with minimal symptoms. Recurrence rates were also equal in both groups. The most recent of these studies also shows that repeat attempts at needle aspiration after an initial failed attempt are of no use. In those instances, a chest tube is warranted.

Needle aspiration of a pneumothorax can be accomplished by using the widely available disposable thoracentesis kits. Local anesthetic is used to anesthetize the skin and subcutaneous tissues in the area of the second intercostal space in the ipsilateral midclavicular line. The small-bore catheter, loaded on the aspirating needle, is guided carefully into the pleural space just above the upper edge of the third rib. Suction on the syringe is applied as the needle is inserted, and once air is aspirated, the catheter can be advanced over the needle, which is ultimately withdrawn. With a syringe and three-way stopcock or one-way valve attached to the catheter, air is aspirated until no more can be evacuated. The catheter is then removed, and a postprocedure CXR is performed to assess the adequacy of the aspiration. If the pneumothorax has resolved, a delayed CXR can be obtained at 6 hours to confirm resolution. The patient can then be followed as an outpatient and reassessed in 24 to 48 hours with a clinical examination and repeat CXR. If, however, on the initial postaspiration or the delayed CXR, there remains a moderate-to-large pneumothorax, insertion of a chest tube is warranted. Failure to resolve a pneumothorax after needle aspiration either on initial postaspiration or delayed chest films is likely due to a persistent air leak.

Chest tube drainage is usually advocated for large, asymptomatic or smaller, symptomatic pneumothoraces. The technique has been well described. Proper functioning of the tube requires deliberate directing of the tube in the desired position. For the most part, chest tubes are inserted in the anterior or mid-axillary line in the fourth or fifth interspace and should be guided posteriorly and cephalad. A tube positioned in this manner will drain both air and fluid satisfactorily in the vast majority of cases. The usual pitfall of a tube placed anteriorly is that it will often find its way into the major fissure and cease to function adequately. Failure to adequately resolve a pneumothorax after chest tube insertion should be investigated with a view to ensuring correct positioning. If this is not clear by CXR, a CT scan should be obtained and in most cases will confirm proper or improper tube location.

Acquired pneumothoraces due to blunt, penetrating, or ventilator trauma almost always require chest tube insertion as initial management. These injuries are usually more severe, and symptoms are not likely to resolve with mere observation or simple needle aspiration.

Most spontaneous primary pneumothoraces can be managed effectively by conservative measures: observation, needle aspiration, and/or chest tube drainage. The adjunctive use of chemical pleurodesis (talc, tetracycline, or other pleural sclerosant) is usually not necessary and is less effective than surgical alternatives as discussed later in this chapter. Chemical pleurodesis should only be used in cases of treatment failure where the patient is either unwilling or unable to undergo surgical repair.

**OPERATIVE MANAGEMENT OF PNEUMOTHORACES**

Operative intervention for first occurrences of primary spontaneous pneumothorax is controversial because most resolve with conservative, nonoperative management, and a large number do not recur. However, recurrence of a primary spontaneous pneumothorax does occur, and the risk of recurrence within 4 years has been reported as high as 54%, with increased risk being associated with smoking, increased height, male gender, and age >60 years. The risk of recurrence of a secondary pneumothorax is even higher and is associated with risk factors such as increasing age, pulmonary fibrosis, and emphysema.

The indications for operative intervention for the definitive treatment of pneumothorax are given in Table 12.3. The principle objectives of surgery in these cases are to resect the blebs or bullae and to obliterate the space to avoid further recurrences. The former can usually be accomplished by stapled wedge resection, and the latter can be approached by several means. Pleural space obliteration can be achieved by pleurodesis, either chemical or mechanical, or by parietal pleurectomy.

The findings at the time of operation are variable. In the case of secondary pneumothorax, the underlying disease is the major determinant of operative findings. In primary pneumothorax, the majority have blebs or bullae, usually located in the apex of the upper lobe and sometimes also in the superior segment of the lower lobe. The finding of abnormalities, however, is not universal. A classification of pleural findings has been suggested in which stage I refers to no discernible abnormalities, stage II refers to pleuropulmonary adhesions, stage III refers to blebs/bullae <2 cm, and stage IV refers to bullae >2 cm.

Open thoracotomy via a transaxillary or posterolateral incision is certainly possible with excellent effectiveness (recurrence rates <0.5%) and low morbidity (3% to 11%). In most cases in which surgical intervention is indicated, a thoroscopic approach can also be used and tends to be the procedure of choice. A standard threec-port approach is usually used with single-lung ventilation being obtained by the way of a double-lumen endotracheal tube. The deflated lung is examined, and if blebs are found, these are excised by stapled wedge resection (Fig. 12.5). This is followed by a procedure to obliterate the space by either pleurectomy or pleurodesis. Parietal pleurectomy appears to be the most effective way of achieving pleural symphysis and preventing further recurrences. Pleurectomy is usually accomplished in the apex and carried down to the level of the third or fourth rib or the azygos vein.

If no blebs are found (stage I), after a negative search for other pathology, pleurectomy is usually performed to obliterate the space. A recent retrospective review demonstrated reduced recurrences with the addition of an apical wedge resection. The addition of an apical staple line on the lung may encourage pleural adhesion and obliteration of the space when accompanying an apical parietal pleurectomy. This is our preferred approach as well.

emphysematous patients often have such poor pulmonary reserve that symptoms related to a pneumothorax can be quite marked and severe.

One of the more common problems encountered after chest tube placement is the development of a prolonged air leak. In an effort to avoid the increased morbidity and mortality of operative intervention in these patients, conservative management may be attempted with prolonged pleural drainage with or without chemical (talc) pleurodesis. Operative intervention is sometimes chosen or becomes necessary to definitively treat the persistent air leak. Bullectomy by stapled resection or ligation is the usual procedure used with concomitant parietal pleurectomy or mechanical/abrasive pleurodesis. When possible, this is preferably done by thoracoscopic in an attempt to minimize the postoperative respiratory complications due to the incisional pain of thoracotomy.

Another option in the occasional poor-risk patients who is deemed unable to tolerate surgical resection is the Monaldi approach of intracavitary drainage. This was initially proposed as a treatment of tuberculous pulmonary abscesses and most recently advocated by Goldstraw and colleagues at the Royal Brompton Hospital. In this procedure, a small portion of rib overlying the bulla is excised subperiosteally. The pleura and bulla are incised within a purse-string suture encompassing bulla wall and both parietal and visceral pleurae. A Foley catheter is inserted through this incision, and the purse-string suture is secured overtop of the Foley catheter balloon, which is within the bulla cavity. The catheter is connected to a usual chest drain suction device with underwater seal. This is supplemented by a talc pleurodesis of the bulla cavity and the intrapleural space.

Cystic Fibrosis

There is an approximate 10% incidence of pneumothorax in patients with cystic fibrosis. Due to the nature of their underlying lung disease, these patients may experience severe symptoms that sometimes culminate in a fatal episode. Conservative therapy with or without a chest tube may be the initial treatment of choice for these patients. This alternative is usually undertaken in an effort to avoid pleurodesis in a patient who may subsequently be a candidate for lung transplantation. It should be noted that pleurodesis, although it may increase the technical difficulty at the time of explanting the diseased lungs, does not in and of itself constitute a contraindication to lung transplantation.

Catamenial Pneumothorax

There are many theories as to the etiology of catamenial pneumothorax, the most common manifestation of intrathoracic endometriosis. Diaphragmatic fenestrations often are encountered in these patients. Catamenial pneumothorax can often be treated thoracoscopically with wedge resection of visible endometrial implants and direct suture closure of diaphragmatic fenestrations in addition to either mechanical pleurodesis or parietal pleurectomy. Nonsurgical options include hormonal suppression with gonadotropin-releasing hormone agonists such as leuprolide, oral contraceptives, and bilateral salpingo-oophorectomy.

In a prospective study, only one of eight patients who underwent surgical repair of diaphragmatic defects suffered a recurrence during a mean follow-up period of 6.6 months (range 2 to 15 months). The retrospective analysis of 10 patients with catamenial pneumothorax revealed no recurrences during a mean follow-up of 33 months (range 12 to 48 months) in the five patients treated by diaphragmatic repair. These data suggest that surgical repair of diaphragmatic defects, often requiring only simple suture closure, is associated with an excellent therapeutic outcome.

When we talk about spontaneous pneumothorax, it is necessary, as the authors point out, to distinguish primary spontaneous pneumothorax from secondary pneumothorax because the treatment and approach differ for the two entities. The usual patient who presents with a primary spontaneous pneumothorax is a young man commonly with a characteristic body habitus. These young men tend to be tall and thin and may have a family history of pneumothorax. The initial management needs to be individualized, but many of these patients can be managed with simple aspiration via the second intercostal space and a repeat chest radiograph to confirm the absence of a reaccumulation of air. Even if an air leak is suspected, initial management may consist of placing a small cannula connected to a Heimlich (one-way) valve and outpatient management. For a first primary spontaneous pneumothorax, we proceed to operation only if the air leak lasts >48 hours or if the patient’s occupation makes travel to remote areas likely. The chance of a recurrence approaches 30%, and thus there is a 70% chance that the patient will never have another pneumothorax. Either a recurrence on the ipsilateral side or a contralateral pneumothorax is an indication for operation. If the second pneumothorax occurs on the contralateral side, consideration should be given to operation on both sides. The operation may be done thoroscopically or open, but I prefer a “hybrid” operation that involves a small transaxillary incision with visualization afforded by placement of the videothoracoscope through the chest tube site. Graspers and a stapling device may be placed via the transaxillary incision because the interspace, usually the second, is quite wide. Apical bulla may be stapled and mechanical pleural abrasion, which is our preference, carried out. I tend to avoid apical pleurectomy because of the increased risk of bleeding, but this procedure may be readily carried out via the transaxillary incision.

Secondary spontaneous pneumothorax, usually occurring in the patient with significant emphysema and potentially bullous disease, requires a different approach than the one just discussed. Most of these patients are poor operative candidates, and conservative management with chest tube drainage often is the preferred approach. Thoracoscopic localization of the air leak often is difficult, and frequently the outcome of an operation is the creation of additional air leaks. If a residual space is present despite adequate chest tube placement and there is continued air leak, the mobilization and transposition of a serrat anterior muscle flap into the space may be the treatment of choice, with the obliteration of the space likely to effect closure of the air leak. The approach to the patient with a secondary spontaneous pneumothorax must be individualized based on the patient’s underlying clinical status and intrathoracic findings as demonstrated on a CT scan.

I would be remiss in not expanding on the issue of tension pneumothorax. The term tension pneumothorax is often misused based on a lack of understanding of the underlying physiology. The simple loss of the normal negative intrathoracic pressure leads to the entry of air into the hemithorax. This may or may not be accompanied by an ongoing parenchymal air leak. If the air leak is small, air accumulates in the pleural space and often in the soft tissue, that is, there is subcutaneous emphysema. A significant air leak usually caused by blunt or, more likely, penetrating trauma can lead to an accumulation of enough air in the chest that the mediastinum shifts and venous return to the heart is compromised. This is the definition of a “tension” pneumothorax. An air leak in a patient on positive-pressure ventilation frequently may be accompanied by tension physiology and requires emergent decompression of the pleural space with a needle placed in the second intercostal space followed by placement of a chest tube. It is the hemodynamic compromise that not only characterizes a tension pneumothorax but also threatens the patient’s life, so emergent recognition and appropriate management are key.

The key to treating giant bullous disease is differentiating a giant bulla from advanced emphysematous changes that results in hyperlucency that may mimic the appearance of a giant bulla. In evaluating a giant bulla, it is critically important to determine if there is a significant amount of compressed lung parenchyma

(continued)
that, with excision of the bulla, may re-expand to completely fill the residual space. A CT scan is the imaging modality of choice to evaluate the amount of underlying lung compressed by a bulla and provides the information on which to base a decision as to whether operation is likely to benefit the patient. Significant improvement in pulmonary function and relief of dyspnea may occur in the well-selected patient where the excision of a bulla allows for functioning lung to re-expand and participate in gas exchange. Simply resecting emphysematous destroyed lung is unlikely to be of benefit unless the changes are heterogeneous and localized to the upper lobe in which case the procedure is termed lung volume reduction.  

LRK
INTRODUCTION

Mediastinal tumors are relatively rare and can be of various origins. Their appearance is often variable, and there is overlap among different tumors. Therefore, it takes many years before one has seen enough of most types to be able to recognize patterns and develop an efficient clinical approach. This chapter presents a practical and logical approach for the workup of anterior mediastinal masses with a focus on thymic tumors, which are the most common and are the primary focus for thoracic surgeons.

The incidence of mediastinal tumors is difficult to define. This is due in part to the inclusion of benign cysts and lesions in some series and not in others. Probably most important, it is due to the inclusion of varying numbers of patients with lymphomas. Although about 50% of Hodgkin disease (HD) and 20% of non-Hodgkin lymphomas (NHL) involve the mediastinum, only about 3% of HD and 6% of NHL involve the mediastinum exclusively. While inclusion of the latter groups as mediastinal tumors seems legitimate given the diagnostic issues they present, inclusion of the former group seems inappropriate if there are enlarged lymph nodes elsewhere, such as in the neck or axilla, which are more easily accessible for biopsy.

CLASSIFICATION OF THE MEDIASTINUM

Several classification schemes for mediastinal compartments have been used. The scheme proposed by Shields is recommended and is currently used most frequently. It is based on anatomic landmarks and is easiest to translate to a computed tomography (CT) scan. This definition describes an anterior compartment, a visceral compartment, and a bilateral paravertebral compartment (Fig. 13.1). The anterior compartment extends between the posterior aspect of the sternum and the anterior surface of the pericardium and the great vessels. The visceral compartment includes the heart, great vessels, trachea, and esophagus, and is bounded posteriorly by the anterior spinal ligament (anterior surface of the vertebral bodies). The paravertebral compartment extends from this boundary to the posterior ribcage.

GENERAL APPROACH TO PATIENTS WITH ANTERIOR MEDIASTINAL TUMORS

Most of the literature regarding mediastinal tumors has been in the form of retrospective series of patients with a specific known diagnosis, and reported on characteristics of the patients. This is contrary to the clinician’s needs, who already knows about the clinical characteristics of an individual patient in question and is trying to ascertain the diagnosis. This chapter therefore starts with clinical features that are clearly defined (age, gender, location of the lesion), and some features that may be well defined (duration of symptoms, associated conditions or features, particular radiographic characteristics). Additional features may be clinically occult, but can be brought out by appropriate testing (laboratory results).

The approach begins with a history and physical exam. The degree and duration of symptoms and the presence of associated diseases can provide important clues to the diagnosis. This is supplemented with a CT scan of the chest. For mediastinal masses the CT scan should always be done with intravenous contrast in order to better define the relationship of the mass to the normal (vascular) mediastinal structures. The chest radiograph (CXR) and CT allow the tumor to be assigned to one of the mediastinal compartments. Although many tumors may overlap somewhat and not be completely restricted to a single compartment, in general the epicenter of the lesion or the bulk of the mass clearly falls within one of the mediastinal areas.

The anterior mediastinum is the most common site of mediastinal tumors, and generally presents the greatest clinical challenges in making a presumptive diagnosis. Overall, data from large series show the approximate relative proportion of tumors that occur in the anterior mediastinum to be thymoma 35%, benign thymic lesions 5%, lymphoma 25% (HD 13%, NHL 12%), benign teratoma 10%, malignant germ cell 10% (seminoma 4%, nonseminomatous germ cell tumor [NSGCT] 7%), and thyroid and other endocrine tumors 15%.

Assessing the clinical characteristics and presentation and defining which mediastinal compartment a tumor is in is an important step in the strategy of how to approach these patients. Despite the variety of tumors, a reliable clinical diagnosis often can be made using the combination of demographic factors, symptoms, and radiologic findings. In many cases, a presumptive clinical diagnosis can be made with sufficient confidence to justify proceeding with a treatment plan without further confirmation.

Patients over Age 40

The proportion of anterior mediastinal tumor types by decades of age for men and women over age 40 is shown in Figure 13.2A and 13.2B. Small differences by age and gender exist, but overall thymoma is the most likely tumor type. With increasing age, substernal thyroid goiters also account for a substantial proportion. Thyroid masses are generally easily and reliably recognized by a characteristic radiographic appearance (high density), continuity with the thyroid gland, and extension posterior to the great
vessels. In rare instances, an iodine 133 scintigraphy scan can be useful, although it must be remembered that an iodine scan is likely to have decreased sensitivity when performed within approximately 4 weeks of a CT scan involving iodinated contrast.

Many patients (30% to 50%) with a thymoma will have an associated parathyroid condition (e.g., myasthenia gravis [MG], hypogammaglobulinemia, pure red cell dyscrasia), which is virtually pathognomonic that an anterior mediastinal mass is a thymoma. In general, tissue confirmation of a thymoma or substernal goiter is not needed prior to resection.

The small remaining subset of patients (especially men and those aged 40 to 49) includes a variety of relatively rare tumors that require histologic confirmation for diagnosis. Preferably, the initial approach is a needle biopsy, but because of the variety and rarity of these tumors this may or may not be sufficient to reliably establish the diagnosis.

Women Aged 10 to 39

In women aged 10 to 39, the most prevalent tumor is HD or mediastinal large cell NHL (MLC-NHL) lymphoma (Fig. 13.3). Many have constitutional symptoms suggestive of lymphoma. In addition, although the epicenter of the mass is in the anterior mediastinum, there is often a fairly characteristic enlargement of multiple lymph nodes in the middle mediastinum and neck. Therefore, a clinical diagnosis of HD or MLC-NHL can be made quite reliably in a large proportion of women aged 10 to 39. However, this must be confirmed by a tissue biopsy. Although one may attempt a needle biopsy first, in most institutions this will be insufficient for full lymphoma characterization and a surgical biopsy will be needed (see later section on biopsy procedures).

A substantial portion of the remaining patients have a thymoma, especially those over age 20. Once again, due to the frequent occurrence of parathyroid conditions that are essentially pathognomonic for thymoma, many of these patients can be very reliably identified on clinical and radiographic grounds.

The other tumor seen relatively infrequently compared to thymoma or lymphoma is a benign teratoma that can be easily identified based on radiographic and clinical features. Most are asymptomatic and when present, symptoms are typically long-standing (29% chest pain, 25% cough, 22% dyspnea, 9% pleural effusion, 1% superior vena cava [SVC] syndrome in 305 patients). The key radiographic feature is a focus of fat density, which is present in about 50%. These tumors are usually rounded with sharp margins, appear well encapsulated and cystic, and contain material of variable density, especially fat, soft tissue, and cartilage. Although 25% have calcification, less than 10% have areas resembling a bone or a tooth. Only 5% of benign teratomas are not in the anterior mediastinum (usually posterior).

Among the remaining patients, a small percentage has substernal thyroid goiter (easily recognized on a CT). In the 20 to 29 age group, about 5% of tumors in women are primary mediastinal germ cell tumors and in this group checking for elevation of alpha fetoprotein (AFP) and β–human chorionic gonadotropin (β–HCG) can be worthwhile (especially if the presentation is atypical for the more common lesions). Especially in the 10 to 19 age group, lymphoblastic NHL must be considered. These typically exhibit fulminant growth, rapid onset of symptoms, present with a large inhomogeneous mediastinal mass and often a pleural effusion. Cytologic findings are quite characteristic and sufficient to establish the diagnosis.

Men Aged 10 to 39

For men aged 10 to 39 there is no dominant tumor type (Fig. 13.3B); however, strong clues can usually be obtained from a clinical history. The rapidity of the onset of symptoms is usually the best marker. Features that are truly pathognomonic, however, are limited to a markedly elevated serum AFP or β–HCG levels, which are quite consistently found only in NSGCT and MG and establish an anterior mediastinal mass as a thymoma.

A rapid onset of symptoms (over days to several weeks) strongly suggests either NSGCT or lymphoblastic non-Hodgkin lymphoma (LB-NHL). Radiographically a bulky, inhomogeneous mass is usually seen in both, sometimes with areas of necrosis or hemorrhage. LB-NHL is more common in ages 10 to 20, and is often accompanied by a pleural effusion, “B” symptoms (fever, night sweats, weight loss), and an elevated serum lactate dehydrogenase (LDH) level. With NSGCT, however, pulmonary metastases are often seen but pleural effusions are uncommon.

The diagnosis of NSGCT is made easily and reliably by demonstrating markedly elevated serum AFP or β–HCG levels. This is present in 90% of NSGCT. A needle biopsy to confirm the diagnosis is not needed in experienced centers when the presentation is typical, as further subtyping of the tumor does not alter the treatment approach. The diagnosis of lymphoblastic NHL is usually easily made from a fine-needle aspiration of the primary mass or a pleural effusion due

---

Fig. 13.1. Classification of regions of the mediastinum.
Children Aged 0 to 9

The proportion of anterior mediastinal tumor types in children aged 0 to 9 are shown in Figure 13.4. There is no dominant tumor type. A rapid onset of symptoms suggests LB-NHL, an intermediate onset suggests HD/MLC-NHL, and more chronic symptoms a thymoma or teratoma. The same specific clinical symptoms, radiographic features, and laboratory tests as discussed in the previous section also apply to this age group. The selection of what confirmatory test to pursue is also the same.

Thymic Tumors

Clinical Presentation

Thymomas are relatively rare and usually indolent tumors that present with vague and subtle symptoms. Thymomas have been reported from ages 8 to 94 years. A broad peak is noted from 35 to 70 years. Patients with MG tend to present at a slightly younger age. While one-third of patients with thymoma present with MG, another one-third are asymptomatic. Approximately 40% of patients with thymoma present with local symptoms, while 30% have systemic symptoms. Cough, dyspnea, and chest pain are the most common symptoms. Dyspnea can result from local compression as well as from the neuromuscular effects of MG. Parathyroid syndromes are common and aid in diagnosis (e.g., MG in 30%, pure red cell aplasia, and hypogammaglobulinemia in 2% to 5% each).
Chapter 13: Diagnostic Evaluation of Anterior Mediastinal Masses and Clinical and Surgical Approach to Thymic Tumors via Sternotomy

Anterior Mediastinal Tumors: Women Age 10–39

Fig. 13.3. Anterior mediastinal tumors in patients age 10 to 39; proportion of tumor types by decades of age: (A) women and (B) men. HD/MLC-NHL, Hodgkin disease/mediastinal large cell non-Hodgkin lymphoma; LB-NHL, lymphoblastic non-Hodgkin lymphoma; NSGCT, nonseminomatous germ cell tumor.

Imaging Characteristics

Radiographically, CT scan has high sensitivity (97%) in detecting these tumors. Intravenous contrast is helpful in determining vascular anatomy and relationship with the tumor. Thymomas typically appear as well-defined round or oval masses, generally anterior to the great vessels but can wrap around these structures. Curvilinear calcifications are seen in 10% to 20% of patients. Extension into mediastinal fat or pleura can be suggested on CT, however, is unreliable. The presence of smooth or lobulated contour, homogeneous enhancement, absence of areas of low attenuation, absence of pericardial or pleural effusion, and absence of calcification in the tumor favor the presence of a thymoma or a well-differentiated thymic carcinoma. A recent study showed that tumors that are greater than 7 cm in greatest diameter, infiltrate mediastinal fat, and have lobular appearance are more likely to be stage III/IV thymomas. Tumor size had the most robust association with advanced stage. In addition, pleural nodules were associated with stage IV disease.

Diagnosis

Using the combination of symptoms, associated conditions and radiologic findings, most thymomas can be reliably differentiated from other anterior mediastinal masses. A clinical diagnosis of thymoma is sufficient to plan operation for localized tumors. Tissue diagnosis is recommended for extensive tumors that require neoadjuvant chemotherapy or if a nonoperative approach is planned. Sometimes it is difficult to differentiate thymoma from lymphoma due to lack of symptoms and equivocal radiologic findings; in this case open surgical biopsy is recommended.

Tissue diagnosis can be achieved through FNA or open biopsy (anterior para-sternal mediastinotomy, thoracoscopy). The success rate is higher with open biopsy (90%), as compared to FNA (62%). Standards for performance and reporting of microscopic findings of needle biopsies of suspected thymomas have been established and should be followed. The suspicion of tumor seeding at biopsy site or needle tract is not substantiated by evidence or the experience at major centers where this has been commonly performed.

Histologic and Stage Classification

Despite their indolent behavior, and frequent lack of malignant cytologic features, all thymomas (regardless of initial stage or histologic type) have been noted to develop extrathymic invasion, local recurrence, and metastasis after resection, and therefore should not be labeled as “benign” tumors. The majority of thymic tumors have nonmalignant-appearing thymic epithelial cells mixed with variable proportions of lymphocytes. A small proportion of cases has cells with malignant features and is labeled as thymic carcinoma. These tumors account for less than 10% of cases in surgical series and about 15% overall and have more aggressive local and systemic behavior and worse prognosis. The World Health Organization (WHO) classifies thymic tumors as type A, AB, B1, B2, B3, and thymic carcinoma. However, tumor heterogeneity is common, and application of the WHO classification has been found to be associated with significant interobserver variability.

Multiple staging schemes have been proposed; the Masaoka classification with Koga modification is endorsed as the current international standard by the International Thymic Malignancy Interest Group (ITMIG). The scheme (Table 13.1) is focused on local extension of the primary tumor with less emphasis on nodal involvement (this is the natural history of majority of thymomas, while thymic carcinomas can have nodal spread).
Anterior Mediastinal Tumors: Children

![Fig. 13.4. Anterior mediastinal tumors in children under age 10: proportion of tumor types by years of age. HD/MLC-NHL, Hodgkin disease/mediastinal large cell non-Hodgkin lymphoma; LB-NHL, lymphoblastic non-Hodgkin lymphoma.]

In general, approximately 40% of thymomas present as stage I lesions, 25% each at stages II and III, 10% at stage IVa, and 1% to 2% at stage IVb. Invasion into mediastinal tissue (stage II, III) is present in 50% of thymomas, with pleural invasion being most commonly followed by pulmonary and pericardial invasion. Approximately 30% of these cases have involvement of the innominate vein or SVC and 20% have phrenic nerve involvement. Direct extension is also seen into the aorta and pulmonary artery (11%) and chest wall (8%).

**Surgical Resection**

Perioperative care should involve specific anesthetic considerations and neurologic consultation in the case of MG. Preoperative medical optimization is critical. Plasmapheresis has been shown to improve postoperative recovery and outcomes in myasthenic patients. Postoperative complications have been reported in approximately 19% (range 7% to 32%) of cases in series including patients with and without MG. These mostly include pneumonia, respiratory complications, and exacerbation of myasthenia. With modern perioperative care operative mortality is less than 1%.

The standard surgical approach for resection of a thymoma is a median sternotomy because of the following factors: (1) all thymomas are malignant tumors; (2) it is critically important to perform a complete resection; and (3) it remains to be demonstrated that the excellent results with open resection can be duplicated by other approaches. The standard approach also involves a total thymectomy, although the evidence and rationale for this are weak. Especially in patients with MG, an extended thymectomy (includes en-bloc resection of thymus gland and surrounding areolar tissue and fat) is recommended due to frequently found ectopic rests of thymic tissue in the surrounding mediastinal fat, although the data are only suggestive of a benefit with this approach.

A complete resection has consistently been found to be of major prognostic importance in the treatment of thymomas of every stage. This means that surgeons should make every effort necessary during the resection to achieve this, with no hesitation to resect additional structures. Furthermore, it means that a surgeon should not embark on an operation if there is the possibility of needing to resect a structure he/she is not prepared to deal with (e.g., chest wall, SVC). The opportunity to cure a patient of a malignant disease is often lost because of an intraoperative compromise resulting from a lack of understanding of the nature of the thymoma and limited anticipation of potential intraoperative findings. There should be a low threshold to refer the occasional patient with a higher stage thymoma to a larger center if there is a possibility of encountering situations beyond an institution’s routine experience.

Standards for exploration of the role of a minimally invasive approach to resection of a thymoma have been published. A minimally invasive approach for what may be a thymoma should only be done in experienced centers, should not compromise the oncologic principles (complete, en-bloc resection of the thymus and any potentially involved adjacent structures), should avoid disruption of the specimen, mark the orientation and the location of any potentially questionable margins on the specimen, and be willing to convert to an open procedure without hesitation if any oncologic principles are compromised.

**Operative Technique**

After performing a standard sternotomy and placement of sternal retractor, the thymus gland is exposed and an assessment of tumor burden and involvement of extrathymic sites is performed. It is often easiest to begin with the right lower pole of the thymus; this is mobilized away from the pericardium and diaphragm. Even in the absence of gross tumor involvement, the fat pad lying in this region should be resected with the gland. All fatty tissue is removed from the surface of the pericardium using blunt dissection. The right pleura reflection is opened and the phrenic nerve is identified. The pleura is incised starting at the inferior portion of the right hilum toward the apex of the chest staying about 1 cm anterior to the phrenic nerve. The pleura is typically resected as the lateral most margin of dissection, along with the adjacent fatty tissue, which is swept medially and anteriorly by blunt dissection, separating it from the nerve. It is useful to place a marking stitch on the mediastinal pleural surface because it can be very difficult for the pathologist otherwise to identify it.

If there is any suspicion of involvement of the lung or pericardium, a portion of these tissues should be resected en bloc with the tumor. One should be very hesitant to categorize such abutment as adherence and to sharply separate the tissues. Furthermore, frozen section examination is notoriously inaccurate for thymoma invasion and should be used with caution. There is little downside to performing a wedge resection of the lung or resection of the anterior pericardium.

In case of unilateral abutment of the tumor against the phrenic nerve, the nerve should be resected unless there is significant preoperative respiratory impairment. If the phrenic nerve is encased unilaterally it should be resected (usually it is already not functioning). If both nerves are involved, one nerve must be preserved, either by sharply dissecting the skeletonized nerve from the tumor or rarely by performing a subtotal tumor resection (in which case one should have probably not attempted resection in the first place). However, there

</thead>
</table>
| I     | Grossly and microscopically completely encapsulated tumor  
This includes tumors with invasion into but not through the capsule, or  
Tumors in which the capsule is missing but without invasion into surrounding tissues |
| IIA   | Microscopic transcapsular invasion  
Microscopic transcapsular invasion (not grossly appreciated) |
| Ib    | Macroscopic invasion into thymic or surrounding fatty tissue, or grossly adherent to but not breaking through mediastinal pleura or pericardium  
Gross visual tumor extension into normal thymus or perithymic fat surrounding the thymoma (microscopically confirmed), or ...  
Adherence to pleura or pericardium making removal of these structures necessary during resection, with microscopically confirmation of perithymic invasion (but without microscopic extension into or through the mediastinal pleura or into the fibrous layer of the pericardium) |
| III   | Macroscopic invasion into neighboring organ (i.e., pericardium, great vessel, or lung)  
This includes extension of the primary tumor to any of the following tissues:  
Microscopic involvement of mediastinal pleura (either partial or penetrating the elastin layer);  
Microscopic involvement of the pericardium (either partial in the fibrous layer or penetrating through to the serosal layer);  
Microscopically confirmed direct penetration into the outer elastin layer of the visceral pleura or into the lung parenchyma;  
Invasion into the phrenic or vagus nerves (microscopically confirmed, adherence alone is not sufficient);  
Invasion into or penetration through major vascular structures (microscopically confirmed);  
Adherence (i.e., fibrous attachment) of lung or adjacent organs only if there is mediastinal pleural or pericardial invasion (microscopically confirmed). |
| IVa   | Pleural or pericardial metastases  
Microscopically confirmed nodules, separate from the primary tumor, involving the visceral or parietal pleural surfaces, or the pericardial or epicardial surfaces, |
| b     | Lymphogenous or hematogenous metastasis  
Any nodal involvement (e.g., anterior mediastinal, intrathoracic, low/anterior cervical nodes, any other extrathoracic nodes)  
Distant metastases (i.e., extrathoracic and outside the cervical perithymic region) or pulmonary parenchymal nodules (not a pleural implant) |

ITMIG, International Thymic Malignancy Interest Group.

is limited data that substantiates these recommendations. In a series of 18 stage III patients, Yano et al. reported a lower tumor recurrence rate after phrenic nerve resection (as well as reduced vital capacity and forced expiratory volume in 1 second). However, no difference in overall survival was noted in the two groups.

Dissection is continued cephalad, dissecting under the insertion of the strap muscles on the undersurface of the manubrium. Tissue is swept medially, taking care to not inadvertently injure the right internal mammary vein. As this is continued cephalad the right upper pole of the thymus begins to emerge. It is dissected from the surrounding fat and traced toward the thyroid using blunt dissection. Generally, the upper pole attachments thin out and break off; otherwise they can be ligated close to the thyroid gland. The free upper pole is then reflected downward and the upper mediastinal fat surrounding the innominate vein is carefully dissected to free up the gland. During this dissection, the thymic artery is ligated. Small venous tributaries draining into the innominate vein are also ligated. A similar technique is then used to dissect the left side of the gland. The dissected tissue can be lifted up or inverted to dissect the underlying mediastinal fat. The pleural spaces should be inspected, and appropriate nodal stations sampled if not already resected and marked. The sternum is approximated using steel wires, after placement of chest tubes.

Standards have been established by ITMIG to promote better surgical outcomes and to better define pathologic reporting of results. The main principles are marking and orientation of the specimen, clear communication with the pathologist, and a systematic approach to nodes and adjacent structures, and documentation. During dissection, any areas of concern (close margin, tissue disruption) should be marked immediately on the specimen as well as in the patient. The resected specimen should be oriented by the surgeon, and given to the pathologist on a medias­tinal board or diagram. Several aspects of the specimen should be routinely identified (tissue adjacent to the innominate vein, pericardium, and the mediastinal pleura). Areas of intraoperative partial disruption of the specimen should be marked and communicated to the pathologist so that there is no misrepresentation of such an area as a positive margin. A sketch or digital photo of the specimen and marking sutures is encouraged (Fig. 13.5).

Any mediastinal or surrounding lymph nodes that carry clinical suspicion of tumor involvement (firm, enlarged, or FDG avid) should be resected and appropriately marked. For small encapsulated tumors, resection of anterior mediastinal and adjacent nodes is encouraged. For stage III and IVa tumors, an anterior mediastinal lymphadenectomy is recommended and a systematic sampling of intrathoracic nodal stations is encouraged. For thymic carcinoma at least a systematic sampling is recommended of anterior mediastinal, intrathoracic, supraclavicularly, and low cervical nodes.

**Handling the Specimen**

Marking the specimen during the course of resection, as noted above, is important. Orientation of the specimen by the surgeon and communication with the pathologist is critical to obtaining a pathology report that can be interpreted clearly. Standard areas that should be marked especially for large tumors, include “surface adjacent to pericardium and innominate vein,” “surface adjacent to SVC,” and “surface adjacent to pleura,” if these structures are not resected en bloc. If marking stitches are used, they
should be placed deep into the specimen to avoid tearing the loose areolar tissue on the surface. Area of potentially positive margins must be marked and communicated to the pathologists, as well as areas that do not represent a true margin, but in which the tissue overlying the tumor is either absent or has been disrupted during the dissection.

There are also standards for how the pathologist should process and report the findings. Surfaces should be identified with different color inks or a similar technique. Because of the heterogeneity of thymoma, at least five sections should be taken to improve the reliability of defining the histologic type. There are also standards for the pathologists to follow in reporting the status of the capsule, the margins, and the distance to the margins that address issues specific to thymoma that have created confusion in the past.

Survival after Resection

Various outcome measures have been reported, which cause fairly dramatic differences and limit the ability to compare past publications; standards have been established to promote comparisons and collaboration. Because many thymomas are relatively indolent, both 5- and 10-year outcomes should ideally be reported (however, 5-year outcomes are sufficient for thymic carcinoma).

Overall, 10-year survival rates of 90% for stage I and 70% for stage II thymomas are typical. The vast majority of these cases is amenable to complete resection. The majority of deaths in patients with stage I or II thymoma is due to unrelated causes. Overall survival with or without complete resection is 55% for stage III and 35% for stage IVa; however, R0 resections result in longer survival. The most important factors that predict survival are tumor stage and completeness of resection. The presence of MG is not an independent prognostic factor; however, MG may play a role in detection of tumors at an early stage due to the presence of symptoms.

Recurrence Rates

Given the fact that recurrence is not always associated with death and vice versa, the best outcome measure for thymic malignancies is probably freedom from recurrence. Resected stage I tumors have average recurrence rate of 3%, which increases to 16% for stage II and 26% for stage III. Variable recurrence rates are noted for stage IV tumors. The mean time to recurrence was reported as 10 years for stage I and 3 years for stages II to IV.

Local recurrence is more common than extrathoracic recurrences. However, what has been classified as a local recurrence has varied among studies; a standard definition for future reports has been developed. A pleural and/or pericardial nodule is the most common recurrence pattern. Distant metastases are seen most commonly in liver and bone.

Factors associated with a lower rate of recurrence are Masaoka stage I and II, histologic type (especially thymoma vs. thymic carcinoma), smaller tumor, and a complete resection.

Preoperative Therapy

There are no randomized trials involving preoperative chemotherapy; however, retrospective studies have shown promising results. Several series have consistently reported increased R0 resection rates after preoperative chemotherapy (72%), as compared to surgery alone (50% for stage III, 25% for stage IV). Chemotherapy resulted in radiographic objective response rate of approximately 90%, and pathologic complete response rate of approximately 20%. In one series, downstaging (stage III-II) was reported in 16% of patients. Preoperative chemotherapy should be considered for clinical stage III/IVa tumors to increase their likelihood of R0 resection. Chemotherapy has also been used for recurrent thymomas followed by resection or radiation therapy (RT) as a curative-intent strategy.

Most chemotherapy regimens are cisplatin based and are well tolerated. It is recommended that resection be performed within 8 weeks of preoperative chemotherapy. If the patient is not a surgical candidate and curative-intent radiation is planned, it should be initiated within 6 weeks of chemotherapy.

Adjuvant Radiation Therapy

The role of adjuvant RT to the operative field is controversial and various practices have been reported. Since most recurrences are local (intrathoracic), it may seem intuitive to add radiation; however, the recurrent tumor is not always in the surgical bed, but may present as nodules on the parietal pleura and pericardium.

Interpretation of the reported data on adjuvant RT is difficult because of limited number of patients, studies spanning many decades, and frequent reporting of completely and incompletely resected patients together. The recurrence rate for completely resected stage I tumors is low and the data do not suggest this is influenced by adjuvant RT. Therefore, in general, adjuvant radiation is not employed for
completely resected stage I thymomas. For completely resected stage II–III tumors, the data do not clearly indicate a difference in recurrence; in fact in the largest study higher recurrence rates were noted after RT (presumably because the patients getting radiation were considered at higher risk). Several systematic reviews and meta-analyses have reported similar findings.

RT seems to lower recurrence rates in the case of incompletely resected stage III and IV tumors. In particular, RT was noted to decrease mediastinal recurrence after subtotal resection.

**RESECTION OF NONTHYMIC ANTERIOR MEDIASTINAL TUMORS**

Resection of nonthymic anterior mediastinal masses can be performed using similar surgical principles. Some anterior mediastinal tumors, such as lymphoma, are treated with chemotherapy and do not require resection. Nonthymic tumors do not require a complete thymectomy as described for thymomas. Surgical excision must however entail resection of all involved structures, such as pericardium, lung, SVC, and so on, just as described for thymic tumors. Limited resection can be safely undertaken for smaller masses through partial sternotomy.

**SUMMARY**

Thymoma is the most common anterior mediastinal tumor followed by thyroid masses in patients over age 40. The most common anterior mediastinal tumor in women 10 to 39 years old is lymphoma followed by thymoma. In men aged 10 to 39, there is no predominant tumor type; however specific symptoms, chronicity of symptoms, radiographic, laboratory, and pathologic findings can help diagnose the lesion.

Thymomas are indolent, malignant tumors that have a propensity for local spread. Approximately one-third of patients with thymoma have MG. CT scan is highly sensitive in diagnosis and certain features can predict the presence of advanced stage disease. Thymic carcinoma is a rare tumor type that is characterized by malignant histologic features and aggressive tumor invasion. The Masaoka-Koga staging scheme is most commonly used and is based on local tumor invasion.

Excellent 5- and 10-year survival rates are noted for completely resected early stage thymomas. Complete resection is the best prognostic factor for these tumors. While stage I/II tumors undergo primary surgery, preoperative chemotherapy appears to increase the chances of complete resection for stage III/IVA tumors. Postoperative radiation can be considered for patients with residual disease.

**SUGGESTED READINGS**

Kesler KA, Rieger KM, Ganjoo KN, et al. Primary mediastinal nonseminomatous germ cell tumors: the influence of postchemotherapy
Compared to lung tumors mediastinal tumors are rare indeed and the average thoracic surgeon may see only a few in any given year. As the authors point out the two most common lesions seen in the anterior mediastinum are thymoma and lymphoma with the incidence of each varying according to the age of the patient. Thymoma is a rare tumor in children while lymphoma is significantly more common. Differentiating between lymphoma and other lesions remains a critical distinction since surgical resection does not contribute to outcome for lymphoma.

For any lesion other than a well-encapsulated one, it is hard to criticize the surgeon who chooses to pursue an open incisional biopsy either via anterior mediastinotomy or videothoracoscopy. Anterior mediastinotomy can be performed as an extrapleural procedure thus eliminating even the small possibility of intrapleural seeding. Remaining extrapleural is facilitated by removing a portion of the second costal cartilage and simply sweeping the pleural reflection laterally as one approaches the lesion which can be easily visualized. I prefer to use a mediastinoscopy biopsy forceps to sample the lesion, taking care to know exactly where the aorta and pulmonary artery are located. The anesthetic management of patients with large mediastinal masses requires special consideration. Especially in those patients with a mass that has rapidly increased in size, usually a large B-cell lymphoma, the airway may be compromised when the patient is placed supine as airway compression from the tumor may occur. In these situations it is safest to keep the patient in the semi recumbent position and proceed with an awake intubation. These situations are unusual but must be kept in mind.

The authors refer to thymomas as “malignant.” I prefer to use the terms “encapsulated” and “invasive” when referring to these lesions and avoid the term “malignant.” It is difficult to put these lesions into the category of malignancy based on their indolent natural history but we do treat the invasive lesions as if they were “malignant.” Complete resection is the gold standard and, as the authors point out, the surgeon needs to be prepared to take en bloc whatever structures are involved by the lesion. These include portions of the pericardium, lung, superior vena cava, and the innominate vein. If pleural lesions are noted at the time of resection these should also be taken with a parietal pleurectomy. If a phrenic nerve is involved it should be taken if by doing so a complete resection will be accomplished. For locally advanced lesions consideration should be given to obtaining a tissue diagnosis and treating with neoadjuvant chemotherapy prior to surgical resection as there is evidence that what might have been less than an R0 resection may indeed be one following induction therapy. Total thymectomy and not just tumor resection should always be carried out.

The decision to pursue postoperative radiation therapy following resection of a thymoma should be made jointly by the surgeon and the radiation oncologist. The incidence of local recurrence does not seem to be different when patients with resected stage II lesions received postoperative radiation therapy compared to those who receive resection alone.

The decision to resect a substernal goiter needs to be based on patient factors, specifically the patient’s age and whether the patient is symptomatic specifically with airway compromise. Essentially all of these lesions, though appearing to be well within the mediastinum, may be resected via a cervical incision and only very rarely is sternotomy necessary.

Germ cell tumors, in particular non-seminomatous lesions, are initially treated with induction chemotherapy followed by resection to remove all residual gross disease. The histologic findings in the treated lesion determine prognosis as well as the need for additional therapy. Findings range from complete necrosis with no viable cells to mature teratoma to the persistence of tumor with sarcomatous elements. Again the intent of the surgeon should be to accomplish a complete resection. Pure seminomas, though rare, may be treated with primary radiation therapy. These are more commonly seen in testis tumors. Primary mediastinal germ cell tumors in women are exceedingly rare.

LRK
INTRODUCTION

With so much emphasis today being placed on new minimally invasive techniques, it is easy to forget that some minimally invasive procedures have been around for years but seemingly never referred to as such. In a sense, one can make a strong case that transhiatal esophagectomy is a minimally invasive operation since it avoids a chest incision and we have been doing that procedure for many years, thanks to Mark Orringer popularizing it back in the 1970s. Other procedures have been “minimized” with smaller incisions, muscle sparing, and, of course, with the use of endoscopes.

Removal of the nontumorous thymus gland for myasthenia gravis classically involved a median sternotomy and despite the efforts of some to utilize a so-called mini sternotomy, at least a portion of the sternum is still split. Jaretski in New York described even a more “maximal” approach utilizing a neck incision combined with a sternotomy making the case that aberrant “rests” of thymus occurred in locations that even a standard sternotomy might miss (Fig. 14.1). It occurred at least to a few surgeons that performing a sternotomy to remove a normal thymus gland was overkill. Working in the same city, Papatestas resurrected the transcervical approach to thymectomy during the 1970s and 1980s with results, relative to myasthenic symptoms, similar to those obtained via the much larger and more morbid operation. Cooper made a major modification to the transcervical approach by designing a retractor that instead of strictly relying on blind blunt dissection, as practiced by Papatestas, allowed for direct visualization of the anterior mediastinum to assure that all of the thymus gland was removed. Both pleural reflections could be visualized; the inferior extent of the gland and the extension of the gland into the aortopulmonary window could also be directly visualized. The Cooper thymectomy retractor allowed for an extended transcervical thymectomy, an approach more predictable and reliable.

Recognizing that a median sternotomy is a big operation with significant attendant morbidity simply to remove a normal structure that easily dissects away from surrounding structures with blunt dissection further made the case for transcervical thymectomy. However, there remained a significant group of vocal opponents to the procedure based on their contention that a transcervical approach failed to remove the entire thymus gland and certainly would miss rest of the gland that, according to Jaretski, commonly occurred in aberrant locations. The objection fundamentally was based on the contention that complete removal of the entire thymus gland was absolutely necessary if one was to achieve a complete remission of myasthenic symptoms. Whether or not that contention is valid still remains an open question. This has been further called into question since in at least one study it has been shown that in patients with ectopic thymic rests, even when removed, the incidence of complete remission remains significantly inferior to that seen in those who do not have ectopic gland. Thus, in a setting in which no procedure results in 100% remission rates, we need to look critically at the type of operation and specifically at the risk-benefit ratio involved in removing what is essentially a normal structure. It has been our hypothesis that transcervical thymectomy should be the preferred approach for the removal of the thymus gland in patients with myasthenia gravis. We believe that the risk-benefit ratio is favorable enough to make the case that essentially all patients with myasthenia should be offered thymectomy via this approach. Even though neurologists who are concerned about subjecting their patients to a surgical procedure often are swayed when they are informed about the minimally invasive nature of this procedure and the results when compared with the open procedure.

DESCRIPTION OF THE PROCEDURE

No specific preoperative preparation is required prior to proceeding with transcervical thymectomy. As opposed to thymectomy via the standard sternotomy approach, plasmapheresis is not necessary even for those patients with significant symptoms. It has been our practice to allow the attending neurologist to decide whether plasmapheresis should be done and if they wish to proceed the exchanges should be done the week prior to the planned operative procedure. We have patients take their usual medication on the morning of the operative procedure, specifically their anticholinesterase inhibitor and, if still taking it, the corticosteroid. We attempt to wean patients to no more than 10 or at most 20 mg of prednisone prior to operation.

The patient is positioned supine with an inflatable bag behind the shoulders which, when inflated, allows for maximal hyperextension of the neck (Fig. 14.2). In the office during the preoperative evaluation, we assess the degree of neck extension recognizing that in those patients with limitation to extension the procedure is somewhat more difficult with respect to visualization. The skin overlying the neck and chest is prepared in the usual manner and the appropriate draping is carried out. A small transverse incision is made as low as possible in the midline of the neck at the level of the sternal notch and carried down through the subcutaneous tissue and through the platysma down to the level of the strap muscles. It has been my preference to make this incision with a scalpel as opposed to using an energy device. Once the strap muscles are visualized, the midline raphe is identified and incised using the scissors. The midline is opened superiorly as high as possible and inferiorly down to the level of the sternal notch. The ligament traversing the sternal notch is incised with the electrocautery. The sternohyoid and sternothyroid muscles on one side are grasped by the assistant and again
Chapter 14: Transcervical Thymectomy

Thymus

• Fat

Fig. 14.2. The patient is positioned supine with the neck hyperextended. Incision is made at the level of the sternal notch. (Fig. 32.1 from Kaiser LR. Atlas of General Thoracic Surgery. WB Saunders Co; 1997.)

using the scissors dissection is carried closely along the posterior border of the sternothyroid muscle reflecting the muscle carefully away from the underlying tissue, which will be the capsule of the thymus gland. The gland has a definite salmon pink color that easily differentiates it from the surrounding cervical fat and in addition the capsule defines the gland as a separate structure. The gland is followed superiorly to its proximal extent where a small arterial branch will be encountered. A clip is placed and the gland elevated anteriorly while dissecting it away from surrounding structures both medially and laterally. A silk tie is placed at the superior most aspect of the pole of the gland to be used as a “handle” to elevate the gland and apply countertraction (Fig. 14.3). The gland is followed inferiorly to where it intersects with the opposite lobe. As described above, the opposite lobe is reflected away from the strap muscles, followed to its termination superiorly and then dissected away from the surrounding structures moving inferiorly.

As the gland is mobilized from superior to inferior, the innominate vein comes into view at the level of the sternal notch. The gland is carefully lifted anteriorly as it is bluntly dissected off the innominate vein using a peanut sponge. Venous tributaries from the gland to the innominate vein are visualized and are either clipped and divided or ligated and divided (Fig. 14.4). The number and the size of venous tributaries vary significantly from patient to patient but are easily visualized as the gland is elevated and the vein pushed down with the peanut sponge. After all of the venous tributaries have been divided, the gland is completely free of the innominate vein and now using a ball sponge in a ring forceps the gland is bluntly reflected off the pericardium as far inferiorly as possible. With the ball sponge, the gland is bluntly freed away from the sternum anteriorly.

At this point, with the gland separated from the innominate vein following division of the venous tributaries, the Cooper thymectomy retractor is placed. Clamps for the retractor arms are placed over the drapes onto the operating table and the arms are inserted and secured. The retractor blade is placed behind the sternal notch and lifted as far as possible before securing it thus almost lifting the patient off the table. Army-Navy retractors are placed in the lateral aspect of the wound and secured to the retractor with penrose drains as shown (Fig. 14.5). The inflatable bag is deflated to optimize the retraction further facilitating the view into the
mediastinum. Under direct visualization, the right lobe of the gland is bluntly freed away from the right pleural reflection using the ball sponge and the gland is further freed off the pericardium to its termination inferiorly and brought over toward the left side (Fig. 14.6). Once at the inferior extent of the gland is visualized, it can be elevated and brought from inferior to superior. The left lobe of the gland is bluntly mobilized away from the left pleural reflection and followed inferiorly toward the aortopulmonary window. The gland often extends fairly far inferior and must be followed to its termination. This is the most difficult part of the procedure but care must be taken to remove the entire gland. One should be aware that the phrenic nerve can be easily damaged either with the cautery or if sharp dissection is used. Recall that the nerve courses anteriorly at its superior extent in the mediastinum and thus can be easily injured if care is not taken. The nerve usually may be visualized.

By completely freeing up the right lobe of the gland and using it as countertraction, the entire left lobe may be mobilized and elevated from inferior to superior. The entire gland is now completely freed away from the pericardium and brought up superiorly for delivery out of the wound. Occasionally, one or more venous tributaries not previously recognized may need to be divided to completely free up the gland and remove it. If a pleural space has been entered during the dissection, it is easily recognized by ballooning of a pleural reflection with ventilation. A thorough inspection should be made to assure hemostasis, and occasionally a small bleeder may be found in the mediastinal or pleural fat. Care should be exercised in using the electrocautery to avoid thermal injury to the phrenic nerve on either side.

If a pleural space has been entered simply placing a red rubber tube through the pleural rent and bringing it out through the neck allows the air to be removed via a valsalva maneuver just prior to completing the skin closure. The wound is closed in layers and the skin closed with a subcutaneous suture to avoid having to remove sutures. The patient is awakened and extubated in the operating room and then brought to the postanesthesia recovery unit. A chest radiograph is performed to assure no significant residual pneumothorax if a pleural space has been entered. There is no need for any further treatment since there is no ongoing air leak. Myasthenia medications are resumed within a couple of hours and the patient may be discharged home the same day with mild analgesics to be used as needed.

Patients experience mild-to-moderate incisional pain and some have some neck pain from the hyperextension. The pain usually subsides within 2 to 3 days. Patients are reminded that myasthenic symptoms relief occurs over time and the time course may be quite variable with the maximum response not seen in some until two or more
years after thymectomy. The neurologist adjusts medication based on symptoms.

When interpreting the results following thymectomy for myasthenia gravis, one needs to assess the number of complete responses defined as the alleviation of all symptoms with the patient on no medication. That being said, some neurologists prefer to leave their patients on small doses of corticosteroids for the duration. As mentioned above, the number of complete responders increases over time, and there is no predictable time course to a response thus it is critically important when evaluating results in a series to look at the Kaplan-Meier probability of achieving a complete response. We can expect that somewhere between 40% and 50% of patients will achieve a complete response over time, another 40% a partial response with a significant reduction in medication required and only about 10% or 20% fail to achieve any response.

In our series of now over 200 patients with a median follow up of 54 months, the complete response rate is slightly over 40% with another 40% achieving a significant partial response. Looking at the
Kaplan-Meier probability of achieving a complete response, there is a 45% complete response rate at 72 months. The only factor that was statistically significant in terms of predicting response was the preoperative Osserman class. The less severe the disease (lower Osserman class) the more likely to achieve a complete response. Fewer than 20% of patients, when last followed, had no improvement. Interestingly, in our initial series only about 10% of patients remained unimproved but as we gained experience we became less selective in our approach operating on some patients where visualization was severely limited by the inability to extend the neck or by obesity. Morbidity for our series was 7% with only one patient experiencing an injury to a recurrent laryngeal nerve. We observed two pleural effusions, two pneumothoraces, and two wound infections. One patient developed pneumonia.

Cooper looked at the long-term outcome in 52 patients undergoing transcervical thymectomy between 1977 and 1986 with a mean follow-up of 8.4 ± 6.1 years and noted a mean decrease from a preoperative Osserman grade of 2.7 to 0.4 at last follow-up.1

CONCLUSIONS

Extended transcervical thymectomy achieves Kaplan-Meier complete response rates (45%) very similar to those achieved either by sternotomy or combined cervico-sternotomy approach (“maximal” thymectomy) (50%). It is likely that remission rates would be equivalent or better depending on patient selection for transcervical thymectomy. Patients with minimal or no neck extension and obese patients are not ideal candidates for the transcervical approach. Despite the objection by some that transcervical thymectomy is, by definition, going to leave residual thymus gland, at least one study shows that patients with ectopic thymic tissue, even when removed, have decreased remission rates compared with those found not to have any ectopic thymus. Thus, it must be concluded that total removal of all thymic tissue should be the goal but it is likely that small amounts of residual gland may also allow for patients to achieve a complete remission over time.

The transcervical approach may also have applicability for other procedures in the anterior mediastinum. We have used this approach in combination with the endocrine surgeons when an aberrant parathyroid gland is located in the mediastinum. The thymectomy using the Cooper retractor may be done at the same time as the parathyroidectomy precluding a second operation. Complete removal of the thymus gland under direct vision, as opposed to removing it blindly, usually results in identification of the aberrant gland. In addition, we have used the transcervical approach to remove encapsulated thymomas up to approximately 4 cm in size. However, we have no hesitation in opening the sternum if the tumor appears to be invading a surrounding structure or the phrenic nerve on either side is at risk. As long as the tumor is not disrupted and can be completely removed and we do not violate oncologic principals, we feel that the transcervical approach is reasonable. We also have, on multiple occasions, used the approach to obtain a biopsy of an unknown anterior mediastinal mass in lieu of a parasternal mediastinotomy.

Transcervical thymectomy is a hard operation to teach because it essentially is a single operator procedure with only a limited part time view by a trainee. The use of video equipment may facilitate training but most centers do relatively few thymectomies in any given year, thus making it even more difficult to reinforce the technical details. In most centers, with only a few exceptions, median sternotomy, either complete or partial, remains the preferred approach to thymectomy VATS thymectomy is utilized except some, but this operation requires the placement of a double lumen endobronchial tube, lateral incisions that require one to traverse the pleural reflection to get to the mediastinum and limited access to the neck. Others have described the use of the robot for thymectomy taking what essentially is a simple procedure, transcervical, and making it significantly more complex and costly. In this era of minimally invasive surgery, transcervical thymectomy, a throwback to the past, remains a true minimally invasive procedure that requires no expensive equipment.

SUGGESTED READINGS

Dr. Kaiser certainly makes a convincing case for transcervical thymectomy. He is quite correct in avoidance of sternotomy. This can be very helpful if this operation can be done correctly. The fact that many patients done either way do not get complete response certainly makes it much more preferable to do the operation through a smaller incision.

Dr. Kaiser also makes a case that in difficult situations partial or full sternotomy is certainly an appropriate way to do this operation. I think this approach is important and Dr. Kaiser and his group have great expertise at doing this procedure safely.

ILK
Resection of Posterior Mediastinal Lesions
Joseph B. Shrager

The posterior mediastinum is bounded anteriorly by the posterior pericardium and extends posteriorly to the chest wall and laterally to include the costovertebral sulci. It contains the descending thoracic aorta, inferior vena cava and azygous veins, the sympathetic chains, and origins of the intercostal nerves at their nerve roots, and it is generally defined to include the esophagus and associated vagi as well. Most anatomical systems consider only lesions that are caudal to the fourth thoracic vertebral body to be within the posterior mediastinum, with more cephalad lesions resting within the superior mediastinum.

The majority of posterior mediastinal masses occurring in adults are benign. These lesions can be usefully classified according to whether they are cystic or solid on radiographic evaluation. Cystic masses in this region typically represent bronchogenic cysts (Fig. 15.1) or esophageal duplication cysts, whereas solid masses are most commonly benign neurogenic tumors (Figs. 15.2 and 15.3; e.g., schwannomas, neurofibromas, or ganglioneuromas). These neural tumors usually arise from the sympathetic chain or the proximal intercostal nerves, but sometimes the exact anatomical origin does not even become clear intraoperatively. Occasionally, one comes across a patient with a pheochromocytoma or paraganglioma, which arise from the randomly located mediastinal paraganglionic cells and may secrete hormones. At initial office evaluation, one should be alert to the presence of hypertension or palpitations that should dictate measurement of urine metanephrines. Esophageal leiomyomas (benign intramuscular tumors within the esophageal wall) are also generally grouped among the posterior mediastinal lesions. The approach to these lesions and to esophageal duplication cysts differs somewhat from the approach to lesions that are unassociated with the esophagus.

In many cases, posterior mediastinal masses come to light as asymptomatic radiographic abnormalities. They may uncommonly, however, present with signs of infection (in the case of infected cysts), or with dysphagia, chest pain, respiratory complaints, or neurological changes (e.g., Horner’s syndrome from tumors involving the upper sympathetic trunk; lower extremity symptoms from dumbbell tumors) resulting from mass effect on adjacent structures. Esophageal lesions can, of course, cause dysphagia but they too are often asymptomatic.

At present, because of the growing availability of less morbid, minimally invasive approaches to posterior mediastinal masses, most authors recommend resection even when lesions are asymptomatic. I believe that the recommendation about whether to proceed with resection of a posterior mediastinal mass needs to be individualized. Clearly, a symptomatic lesion is best managed by resection, except in unusual circumstances. When an asymptomatic lesion has all of the radiographic characteristics of a benign cyst or tumor (i.e., smooth margins, simple-appearing cyst material, minimally positron emission tomography PET) positive if PET has been done), then the age and general medical condition of the patient should be the key considerations. Since these lesions do generally grow—albeit at a fairly slow rate—it is likely that a young patient will eventually develop symptoms due to impingement on surrounding structures or infection of a cyst. Patients under the age of 60, then, who are otherwise good surgical candidates, are best managed by resection. For older patients, or those who have substantial comorbidities, it is perfectly reasonable to follow these benign appearing, asymptomatic lesions with radiographic studies and operate only if they begin to grow dramatically, the patient develops symptoms, or a change in radiographic appearance suggests malignancy. In any case, there is no urgency to remove these cysts and tumors. The significance of the very few reports of development of malignancy within a benign posterior mediastinal mass is likely overstated.

Surgical Principles
Video-Assisted Thoracoscopic Surgery vs Thoracotomy
Resection of posterior mediastinal masses may be accomplished by means of either video-assisted thoracoscopic surgery (VATS) or thoracotomy. The procedure, apart from the incisions, is essentially the same with either approach, and the goal is complete resection. With some exceptions, VATS is considered preferable to thoracotomy in this setting. It has been well established that VATS results in less postoperative pain and quicker functional recovery. Some surgeons argue that a VATS approach may be more likely to leave a patient with microscopic residual disease. In our experience and that of others, however, recurrences of these lesions are very rare after VATS excision. Given the low recurrence rate and the fact that these masses are almost always benign, we believe that the risk–benefit ratio favors VATS in most cases.

There are, however, several circumstances in which thoracotomy is indicated from the outset. A suggestion of malignancy (in particular, frank invasion of surrounding structures) on preoperative imaging mandates exploration and resection by thoracotomy; in this situation, the potential consequences of positive margins justify the more aggressive approach. The presence of active infection within a cyst is a relative indication for thoracotomy, in that it can cause disruption of normal tissue planes and thereby render VATS dissection more difficult and possibly hazardous. Masses larger than approximately 6 cm also call for an open approach in my opinion: such lesions are typically more difficult to mobilize safely from surrounding structures than smaller lesions, they are more likely to be malignant (though this is still rare), and their removal between the ribs is likely to necessitate substantial rib spreading, which may negate the benefit of true VATS. Another approach is to attempt...
Section I: General Thoracic Surgery

Cyst with a communication, reapproximation of the esophageal mucosa is a paramount consideration; in my view, this is still most reliably carried out through an open approach.

In cases of suspected leiomyoma of the esophagus, preoperative investigation with esophagoscopy should be done to confirm the presence of intact overlying mucosa, which is virtually pathognomonic of this disease. If the mucosa is intact, the possibility of malignancy is essentially ruled out. Simultaneously, endoscopic ultrasonography may be performed to establish the depth to which the esophageal wall is involved. With a preoperative diagnosis of probable leiomyoma, VATS is the approach of choice in our practice.

The so-called dumbbell neurogenic tumors (tumors that invade the neural foramen and have a spinal canal component) are special cases (Fig. 15.4). Any solid mass in the costovertebral sulcus that cannot be clearly separated on CT imaging from the neural foramen should be evaluated by means of magnetic resonance imaging (MRI). Although invasion of the neural foramen by tumor is not in itself an indication for thoracotomy, it does necessitate a combined approach with neurosurgical involvement for the intraspinal portion of the procedure. Several versions of such an approach have been described, including a posterior approach via costotransversectomy or extension of a midline incision into a posterolateral thoracotomy, through which both the intraspinal and intrathoracic components of the tumor can be addressed.

VATS for these larger lesions, but to have a low threshold to convert to thoracotomy if difficulty is encountered. If the dissection can be completed by VATS, one can then typically remove larger tumors by resecting a small portion of the rib without sacrificing an intercostal nerve. It is likely that this will result in less pain and earlier recovery than a standard thoracotomy with rib spreading, but this has to my knowledge never been studied.

Other Preoperative Issues

Any patient with a centrally located cyst should undergo bronchoscopy to rule out the rare occurrence of a communication with the bronchial tree. This may be suggested on computed tomography (CT) scans by the presence of an air–fluid level. If a communication is identified, strong consideration should be made to proceed with thoracotomy rather than VATS. When a cyst arises from or abuts the esophagus, the possibility of a communication between the cyst and the esophageal lumen should be similarly investigated. To rule out this phenomenon, I obtain barium esophagography during the preoperative workup, followed by esophagoscopy in the operating room prior to the start of the operation. If a communication is identified, thoracotomy is performed. After excision of an esophageal duplication cyst with a communication, reapproximation of the esophageal mucosa is a paramount consideration; in my view, this is still most reliably carried out through an open approach.

When a cyst arises from or abuts the esophagus, the possibility of a communication between the cyst and the esophageal lumen should be similarly investigated. To rule out this phenomenon, I obtain barium esophagography during the preoperative workup, followed by esophagoscopy in the operating room prior to the start of the operation. If a communication is identified, thoracotomy is performed. After excision of an esophageal duplication cyst with a communication, reapproximation of the esophageal mucosa is a paramount consideration; in my view, this is still most reliably carried out through an open approach.

In cases of suspected leiomyoma of the esophagus, preoperative investigation with esophagoscopy should be done to confirm the presence of intact overlying mucosa, which is virtually pathognomonic of this disease. If the mucosa is intact, the possibility of malignancy is essentially ruled out. Simultaneously, endoscopic ultrasonography may be performed to establish the depth to which the esophageal wall is involved. With a preoperative diagnosis of probable leiomyoma, VATS is the approach of choice in our practice.

The so-called dumbbell neurogenic tumors (tumors that invade the neural foramen and have a spinal canal component) are special cases (Fig. 15.4). Any solid mass in the costovertebral sulcus that cannot be clearly separated on CT imaging from the neural foramen should be evaluated by means of magnetic resonance imaging (MRI). Although invasion of the neural foramen by tumor is not in itself an indication for thoracotomy, it does necessitate a combined approach with neurosurgical involvement for the intraspinal portion of the procedure. Several versions of such an approach have been described, including a posterior approach via costotransversectomy or extension of a midline incision into a posterolateral thoracotomy, through which both the intraspinal and intrathoracic components of the tumor can be addressed.

Any patient with a centrally located cyst should undergo bronchoscopy to rule out the rare occurrence of a communication with
can be resected. We prefer to perform the following approach: under a single anesthetic, the neurosurgeons first resect the intraspinal component (laminectomy and intervertebral foraminotomy), then the patient is repositioned to lateral decubitus and we carry out the remainder of the procedure (generally via VATS). Failure to diagnose a dumbbell tumor preoperatively and plan an appropriate combined operation may lead to inadvertently cutting through tumor from within the chest. This can result in tumor hemorrhage within the spinal canal and spinal cord compression with disastrous consequences.

Patients with functioning paragangliomas or pheochromocytomas, if hypertensive, should receive approximately 2 weeks of \( \alpha \)-adrenergic blockade and volume loading, followed by \( \beta \) blockade. Clear discussion about the intraoperative anesthetic and anti hypertensive plan should be undertaken between the surgeon and the anesthesiologist in these cases before incision.

There is in the vast majority of cases no advantage to preoperative needle biopsy of posterior mediastinal lesions, although this can usually be readily performed either transhoracically, or via the transesophageal route in the case of periesophageal masses. Only in cases of invasive malignancy might this alter the therapeutic approach. For example, extremely large or invasive-appearing lesions that turn out to be sarcomas may be best treated by preoperative chemotherapy and/or radiation. It is therefore appropriate to obtain a needle biopsy in the unusual cases when these features are present.

Although VATS is often an excellent approach to posterior mediastinal lesions, it must be emphasized that one should never hesitate to convert a VATS procedure to a thoracotomy if required. Accordingly, informed consent to undergo thoracotomy should be sought before operation from all patients being treated for posterior mediastinal lesions, even when VATS is the intended approach. Further, any patient with a tumor encroaching upon the neural foramen should understand preoperatively that there is a very rare possibility of spinal cord compromise from the operation, as well as of cerebrospinal fluid (CSF) leak.

**SURGICAL TECHNIQUES**

**Video-Assisted Thoroscopic Surgery Resection of Neurogenic Tumors of the Posterior Mediastinum**

Resection of a solid neurogenic tumor of the posterior mediastinum that *does not* invade the neural foramen (Fig. 15.3) proceeds as follows. The intraoperative photographs are selected from several separate VATS operations that the author has performed.

**Step 1: intubation and endoscopy.** The patient is intubated with a double-lumen endotracheal tube to allow single-lung ventilation. Preoperative bronchoscopy (for cystic lesions) or esophagoscopy (for lesions abutting the esophagus) is performed as indicated (see above).

**Step 2: patient positioning and placement of ports.** The patient is placed in the lateral decubitus position and stabilized with a bean bag so that the operating table can safely be tilted as much as 45 degree anteriorly. With this degree of tilt, the lung will almost always fall away from the field of vision; thus, there is usually no need to place an additional port for a lung retractor.

The port for the scope is placed through an incision in approximately the anterior axillary line at the level of the mass; if it is placed much more anteriorly than the anterior axillary line, the surgeon’s view of these posterior lesions may be obscured by the lung. The two working ports are placed through separate incisions also in approximately the anterior axillary line, made as far cephalad and caudad as possible. Sometimes, the placement of an alternative upper working port posterior to the scapula is advantageous. The main working instruments are an endoscopic scissors cautery, a ring clamp, an endoscopic peanut dissector, a Maryland dissector, a long right-angle clamp, a hook-cautery, and an endoscopic clip applicer. I prefer a 5 mm, 30 degree thoroscope. The 30 degree lens provides much greater versatility and visualization around to the “far side” of lesions than a 0 degree lens, and a 10 mm scope provides no advantage over 5 mm to justify the increased chance of intercostal nerve injury. I prefer to use 2 cm incisions for the working ports, without gas insufflation, to allow a variety of instruments to be passed without difficulty.

**Step 3: incision of pleura.** The parietal pleura is incised, with a margin of approximately 1 cm circumferentially around the mass (Fig. 15.5). The pleura can be tented up with the aid of the right-angle clamp or the Maryland dissector to separate it from the underlying structures. This separation allows the use of the electrocautery, which provides hemostasis while protecting the underlying esophagus, vagus and intercostal nerves, and azygos vein. This dissection can also be done with the hook-cautery to both create the lift from underlying structures and incise the tissue. This dissection and all subsequent work are facilitated by placing gentle traction on the mass with a sponge stick or, for smaller masses, by grasping the entire mass within a ring clamp to allow manipulation. This sort of manipulation must be minimized in the case of a...
Section I: General Thoracic Surgery

Fig. 15.5. The pleura is incised circumferentially, approximately 1 cm from the tumor.

functioning paraganglioma/pheochromocytoma to avoid marked hypertension.

**Step 4: dissection of soft tissue attachments.** Once the pleura has been incised circumferentially, the soft tissue attachments are further dissected bluntly with the endoscopic peanut dissector. Attachments that are relatively thick or vascular are controlled with the hook-cautery when remote from surrounding structures, or by double-clipping and division when closer to danger. Often, one needs to use cautery to dissect the tumor and associated periosteum cleanly off the surface of one or two ribs above or below the tumor (Fig. 15.6). By progressively dissecting in a circular motion around the tumor, dividing all attachments to the mass, one moves progressively closer to the source of the tumor, most commonly from an intercostal nerve. The attachment to the nerve is typically more easily and safely addressed when most of the other attachments have already been divided. When the mass has been mobilized off of all other surrounding structures, gentle dissection at the medial and lateral margins of the tumor, just inferior to the associated rib, will identify the intercostal bundle (or sympathetic chain) that is the source of the lesion (Fig. 15.7).

**Step 5: division of source intercostal bundle.** The source intercostal bundle, first lateral to the tumor, is mobilized, doubly clipped, and divided (Fig. 15.8). Once this has been accomplished, further blunt and cautery dissection are performed until the nerve root emerging from the neural foramen and the associated intercostal vessels are the last remaining attachments (Fig. 15.9). If the tumor originates from the sympathetic chain, the chain is clipped above and below the tumor, and the intercostal bundle is spared if it is clearly uninvolved.

**Step 6: removal of specimen.** After dividing any remaining soft tissue attachments, the “live” end of the intercostal bundle, medial to the tumor, is dissected and then doubly clipped and divided (Fig. 15.10), and the mass is removed in an endoscopic bag (Fig. 15.11). The typical appearance of the operative field at the end of the procedure is shown in Figure 15.12.

**Step 7: drainage.** A 24F chest tube is positioned posteriorly at the apex.

**Potential Problems and Their Avoidance**
Care must be taken to ensure that only very gentle traction is exerted on a mass adjacent to the neural foramen. Overzealous traction can cause tearing of the nerve root proximal to the extraspinal extent of the dura, and this tearing can lead to a CSF leak, which most often becomes evident only postoperatively (in the form of persistent clear chest tube output). The diagnosis of CSF leakage can be confirmed by measuring the $\beta_2$-transferrin level in the fluid. If CSF leakage is confirmed, reoperation with a neurosurgeon is mandatory; the site of the leak is repaired and buttressed with vascularized tissue.

Fig. 15.6. As additional attachments are dissected, one often must cauterize directly on the periosteum of surrounding ribs to assure a clean resection, as shown here.
Chapter 15: Resection of Posterior Mediastinal Lesions

After resection of a tumor at the costovertebral sulcus, regular neurologic examinations of the lower extremities are indicated. Tamponade with hemostatic agents should never be employed for bleeding at the neural foramen as doing so can result in an intraspinal hematoma with subsequent cord compression. Careful use of the electrocautery at the bony margins of the foramen or watchful waiting is preferable. If hemostasis cannot be achieved with these measures, a neurosurgical consultation should be obtained. In the event of oozing from the vicinity of a foramen that is not easily controlled, there should be no hesitation in converting a VATS procedure to an open procedure.

In a minority of patients, clipping and division of an intercostal nerve result in substantial intercostal neuralgia after the procedure; the possibility that this may occur must be discussed with the patient preoperatively. Many patients who undergo division of a lower thoracic intercostal nerve that supplies an upper abdominal dermatome notice minor postoperative bulging of the ipsilateral abdomen in the area supplied by that nerve.

**Video-Assisted Thoracoscopic Surgery Resection of a Benign Cyst of the Posterior Mediastinum**

Resection of a benign cystic mass of the posterior mediastinum closely resembles resection of a neurogenic tumor (see steps above). One starts by incising the pleura...
Fig. 15.10. At least two clips are placed, as shown here, on the source intercostal bundle medial to the tumor, prior to division.

Fig. 15.11. The specimen is bagged and removed.

circumferentially, then dissects and divides attachments progressively, circumferentially, until the cyst has been completely mobilized. The procedures are typically simpler since there is no intercostal bundle to be concerned with.

Potential Problems and Their Avoidance

In the initial stages of dissection of a benign cyst of the posterior mediastinum, care should be taken not to rupture the cyst; initial mobilization from surrounding structures is far easier when the cyst wall remains under tension (Fig. 15.13). Occasionally, a portion of the cyst wall is found to be inseparable from an important mediastinal structure such as the esophagus or the membranous wall of the airway and cannot be removed safely. This is more common in the case of active or recent infection of the cyst. In these situations, I will intentionally rupture the cyst once that part of the wall is all that remains to be mobilized. I then resect all of the nonadherent portion of the cyst wall and ablate the residual adherent cyst wall with electrocautery to destroy any potential remaining secretory tissue. In rare cases, I have left as much as 35% of the wall of a bronchogenic cyst in place, and I have never seen a recurrence to date. It is my recommendation that if more than approximately 35% of the cyst must be left in place, conversion to thoracotomy should be considered to prevent recurrence.

Resection of Esophageal Leiomyomata and Duplication Cysts

In addition to the steps described above for resection of a neurogenic tumor, there are several special maneuvers that facilitate resection of esophageal intramural masses, such as leiomyomata and duplication cysts.

1. After incising the pleura, the longitudinal esophageal muscle fibers that overlie the mass are separated bluntly or with the electrocautery in the line of the fibers. These fibers are often markedly attenuated as a result of the expansion of the mass.

2. Blunt dissection with an endoscopic peanut dissector allows careful, progressive mobilization of the mass, first from the muscle layer and then from the underlying mucosa. Gentle traction on the mass aids exposure during this portion of the procedure. A suture may be placed into the tumor to facilitate this retraction. Having an assistant place the endoscope within the esophageal lumen to distend and illuminate the mucosa also may be helpful at this stage. Once the mass has been completely resected, it is sent for pathologic examination. Even horseshoe-type leiomyomata can usually be successfully resected by this technique.

3. After resection, the esophagus is distended by insufflating air from above through the endoscope while the distal esophagus is occluded with a sponge stick. The air-filled esophagus is then submerged in saline, and the area of the resection is examined for air leakage.
Chapter 15: Resection of Posterior Mediastinal Lesions

145

Fig. 15.12. The typical appearance of the prior bed of the tumor, following resection.

Fig. 15.13. Dissection of posterior mediastinal cysts away from surrounding structures is facilitated by keeping the cyst wall intact for as long as possible during the resection.

Potential Problems and Their Avoidance

The muscular defect in the esophageal wall must be closed after resection to assure that an esophageal diverticulum does not develop. Such closure may be accomplished by means of thoracoscopic suturing.

Frequently, duplication cysts are more adherent to the underlying esophageal mucosa than leiomyomata are, and transillumination of the esophageal wall helps define the plane at which blunt dissection should be performed. Where the cyst wall becomes difficult to separate from the mucosa, a small amount of the wall may be left in place if, in the surgeon’s judgment, attempting to remove all of it might lead to a breach in the mucosa. In my opinion, if the mucosa is breached, a thoracotomy should be performed to assure precise mucosal and muscle layer repair. All patients should have a gastrograftin/barium swallow to insure mucosal integrity prior to advancing diet on postoperative day 2.

RESULTS

There should be essentially zero recurrences if the principles and techniques described above are followed in the resection of benign posterior mediastinal masses and cysts. Patients are generally discharged on postoperative day 2. The severe complications of spinal cord compression, CSF leak, and esophageal leak should never occur when attention is paid to the details of the procedure. The most common ill effect, in my experience, is intercostal neuralgia when the intercostal nerve requires clipping and division. Since there is no known way to prevent this when the nerve must be sacrificed, patients need to be informed of the possibility, and this possibility needs to be weighed in the decision about whether to proceed with surgical resection or follow these lesions radiographically.

SUGGESTED READINGS

As Shrager points out most of the lesions that occur within the posterior mediastinum are benign and many can simply be followed as opposed to resected. When a decision is made to resect I agree with Shrager that VATS is the preferred approach. The exposure is excellent and once the overlying pleura is incised most of these lesions are easily mobilized. Care must be taken to avoid undo traction on the intercostal nerve so as to avoid avulsion with tearing of the dura and a resultant CSF leak. The extent of the dural sheath on an intercostal nerve varies, so care should be taken to make sure that a clip is placed prior to dividing a nerve if one is close to the neural foramen. When dissecting at the level of the neural foramen one encounters a rich vascular network that may be difficult to control. I avoid the use of monopolar cautery at or near the foramen and rely on bipolar cautery to control this sometimes troublesome bleeding.

As the author points out the occasional cystic lesion that has become infected can be quite adherent to surrounding structures including the esophagus. I completely agree with him that in those circumstances it not only is acceptable but likely safest to leave a portion of the cyst wall intact as opposed to potentially causing damage to another structure.

One cannot stress enough the care that must be taken with the so-called dumbbell lesions, those benign, usually Schwannomas, that have both an extraspinal and intraspinal components. If there is any question of an intraspinal component I obtain an MRI scan and based on the results plan the surgical procedure accordingly. Interestingly, though we often talk about these lesions they are quite rare but when encountered require a collaborative approach between the neurosurgeon and the thoracic surgeons. As Shrager points out, the intraspinal component should be dealt with first followed immediately by excision of the intrathoracic component. Whether one approaches the intrathoracic component by an extension of the posterior incision or repositions the patient and does a separate approach likely makes little difference. Again, a VATS approach is our favored one for the intrathoracic component. Malignant lesions of the posterior mediastinum are extremely rare as are the hormone-producing lesions.
INTRODUCTION

Peptic esophageal injury was first described in the late 19th century, but became more frequently recognized with the advent of upper gastrointestinal endoscopy. The association of peptic esophageal injury and gastroesophageal reflux disease (GERD) was demonstrated in the 1930s. It was not until the association of hiatal hernia and GERD was recognized in the 1950s, however, that antireflux surgery emerged. The 360 degree fundoplication to treat GERD was reported in 1955 by Rudolf Nissen, a Swiss surgeon. Nissen's fundoplication created a long, super competent lower esophageal sphincter (LES), which in turn frequently led to postoperative bloating, dysphagia, inability to belch, and flatulence. In the 1980s, Donahue and DeMeester perfected the short, floppy Nissen fundoplication by dividing the short gastric and retrogastric attachments, shortening the wrap to 1 to 2 cm, and performing the wrap around a large Maloney dilator. By better allowing gas to vent from the stomach, this modification avoided most of the unwanted side effects while still controlling pathologic reflux.

In 1992, the New England Journal of Medicine published a seminal study from the Veterans Administration that showed open Nissen fundoplication to be superior to continuous medical therapy in patients with complicated GERD. That same year, the field of antireflux surgery was revolutionized when Bernard Dallemagne of Belgium and Alfred Cuschieri of Scotland performed the first laparoscopic Nissen fundoplication (LNF). Between 1990 and 1997, the annual rate of LNF more than doubled. Rates have decreased since that time for a variety of reasons, including improper technique and an unacceptable rate of recurrent GERD mainly due to experience on the part of the surgeon. In spite of this, LNF remains the gold-standard treatment of GERD with multiple studies demonstrating control of reflux at 10 years in 90% of patients. Continued successful surgical correction of GERD requires both adherence to proper surgical technique and appropriate patient selection.

INDICATIONS

GERD is the most common disease of the alimentary tract requiring medical or surgical treatment. It affects 7% of adults in the United States on a daily basis and >30% on a regular basis. In addition, 5% to 15% of these individuals experience serious complications of GERD such as esophageal stricture or Barrett’s esophagus. Typical symptoms of GERD include heartburn, regurgitation, and dysphagia. Atypical symptoms include cough, hoarseness, wheezing, and chest pain. Nonoperative treatment of GERD involves lifestyle modifications such as weight loss, avoidance of food intake for several hours prior to retiring to bed, elimination of food and medications that promote LES dysfunction, cessation of smoking, and elevation of the head of the bed. Many patients require pharmacologic treatment such as daily use of proton-pump inhibitors (PPIs). Quality-of-life assessments performed on patients with severe GERD reveal scores similar to patients with chronic congestive heart failure, emphasizing the debilitating effect of this disease.

Patients whose symptoms are refractory to PPIs are candidates for LNF, as are those whose symptoms are controlled on PPIs, but who prefer to avoid life-long need for medication. Studies have demonstrated LNF to be cost-effective in young patients with severe GERD. Those with predominant respiratory symptoms are another group best served with LNF as only 50% have symptom control with medication. That being said, those patients responsive to PPIs and with typical symptoms of GERD have the best outcomes from operation. The current recommendation is to consider operation for heartburn patients responsive to medication, but with frequent troublesome symptoms poorly treated by PPIs, such as regurgitation and respiratory symptoms. Patients with large hiatal hernias are unlikely to have their symptoms of postprandial chest pain and regurgitation adequately treated with PPIs.

A relative contraindication to LNF is morbid obesity (BMI >40), as these patients have an increased risk of recurrent GERD and are better served with a roux-en-Y gastric bypass to not only control their GERD but also for optimal weight loss.

PRINCIPLES OF ANTIREFLUX SURGERY

Prior to offering an antireflux operation, a thorough preoperative evaluation must be completed. In a patient with typical or atypical symptoms of GERD, the diagnosis is confirmed by endoscopic evidence of erosive esophagitis, peptic stricture, or Barrett’s esophagus or by a 24-hour ambulatory esophageal pH study revealing a pH of <4 for >4.2% of the study period. Even with an abnormal pH study, an upper endoscopy is essential to document sequelae of GERD and to rule out other pathology masquerading as GERD. Finally, esophageal manometry assesses esophageal motility. Previously, it was thought that ineffective esophageal motility (>60% ineffective swallows or <40 mmHg mean distal esophageal contraction pressure) was an indication for partial fundoplication, but it is clear now that impaired esophageal bolus clearance after Nissen fundoplication is only a risk in the presence of aperistalsis. Video barium swallow is indicated to evaluate an associated hiatal hernia and/or a shortened esophagus. A nuclear medicine gastric emptying study is recommended in patients with diabetes or symptoms of nausea, vomiting, and early satiety as those found to have delayed emptying will benefit from pyloroplasty at the time of LNF.

The objective of any antireflux operation is to reconstruct a LES that has been rendered mechanically defective due to hypotension, inappropriate relaxation, and/or intrathoracic displacement. Guiding surgical principles include the establishment of an adequate intra-abdominal length of esophagus (>3 cm), reduction and repair of an associated hiatal hernia.
hernia, and tension-free construction of an appropriate fundoplication. All fundoplications should restore the acuteness of the angle of His and calibrate the fundoplication diameter to be loose around an 18 to 20 mm esophageal dilator. There is consensus within the surgical community that a laparoscopic approach is preferred in the vast majority of patients undergoing fundoplication. Thoracotomy is indicated only in specific reoperative settings, where a hostile upper abdomen makes a transthoracic approach appealing.

**PATIENT PREPARATION**

Patients should be maintained on PPIs preoperatively to minimize esophagitis. Peptic strictures should be dilated preoperatively. Anticoagulants and nonsteroidal anti-inflammatory agents are discontinued. Glucose control should be optimized, and cardiopulmonary disease should be thoroughly evaluated with appropriate consultation and testing preoperatively. The patient should be nil per os the night prior to surgery. Perioperative antibiotics are unnecessary as antireflux surgery is a clean operation.

**SURGICAL TECHNIQUES**

**Laparoscopic Nissen Fundoplication**

LNF is generally performed in the supine position with the legs extended and abducted 30 to 60 degrees so that the surgeon may operate between the legs. Low lithotomy is a less desirable position as peroneal nerve injury, deep venous thrombosis, and patient movement while in reverse Trendelenburg position is more frequent. Some surgeons prefer the patient in the supine position, operating from either the left or the right side. This setup, however, results in poor ergonomics with resultant chronic shoulder injuries in the surgeon and the need to address the hiatus obliquely. Clearly, optimal positioning favors a split-leg position. The assistant standing to the left of the patient holds the camera with the left hand and assists with the right hand. The monitor is placed over the patients head ideally fixed on a ceiling-mounted boom (Fig. 16.1).

LNF is performed with a five-port technique. The operation begins by insufflating the abdomen with a Veress needle placed above the umbilicus. After obtaining pneumoperitoneum, an 11-mm trocar is placed 15 cm below the costosternal junction slightly to the left of the midline. By placing the port to the left of midline, and obliquely entering the abdomen—aiming toward the esophageal hiatus—the surgeon minimizes the risk of port-site hernia, stays out of the fatty ligamentum teres, stays further away from the left lobe of the liver, and more accurately aligns the laparoscope with the trajectory of the esophagus (right to left) as it traverses the diaphragm. A 45-degree laparoscope is introduced and a brief abdominal survey is performed. All other trocars are placed under direct vision and all sites are infiltrated with local anesthesia before an incision is made. The second 11 mm trocar is introduced along the left costal margin 12 cm from the base of the sternum. The 11 mm trocar facilitates the passage of suture and is useful for the placement of endoscopic clips when necessary. The third trocar placed is 5 mm, generally located 8 cm farther down the left costal margin than the second trocar but not further lateral than the anterior axillary line. A Nathanson liver retractor is introduced through the track of a cutting 5 mm port that has been placed and removed just inferior and left of xiphoid. The liver retractor is connected to a mechanical arm fixed to the right side of the operating table. The optimal position of the liver retractor allows access to the anterior arch of the hiatus as well as thoroughly defining the right crus of the diaphragm. The patient is then placed in steep reverse Trendelenburg position. The fifth trocar is used for the surgeon’s left hand and is placed along the right costal margin just inferior to the edge of the retracted left lobe of the liver. The point at which this trocar is placed is determined by internal, not external, anatomy, and therefore is variable in its
superficial projection. It is generally desirable to have this trocar as high and as wide as possible without going into the left lobe of the liver or achieving placement to the right side of the falciform ligament.

Dissection commences by the assistant grasping the epiphenic fat pad and retracting inferiorly and slightly toward the patient's left. This reduces any hiatal hernia and places the phrenoesophageal membrane on tension. Next, the surgeon exposes the right crus of the diaphragm by opening the gastro hepatic ligament above and below the hepatic branch of the vagus (Fig. 16.2). While it is desirable to preserve the hepatic branch of the vagus, many surgeons routinely divide it to obtain better access to the right crus. A blunt atraumatic grasper is placed beneath the phrenoesophageal ligament to establish the plane between the esophagus and the diaphragm. This layer is divided with ultrasonic energy (Fig. 16.3). The dissection proceeds around the arch of the hiatus and down the left pillar of the diaphragm as low as is easily visualized. Access to the mediastinum is obtained by placing two blunt graspers (closed) between the esophagus and the right crus of the diaphragm, and then spreading horizontally. This is repeated on the left side of the esophagus. The anterior vagus nerve is generally affixed to the esophagus, and the posterior vagus nerve is not visible at this time. Dissection down the right crus of the diaphragm continues until the surgeon reaches its base where the left crus is visualized emerging from posterior to the esophagus. This completes the preliminary phase of the crural dissection.

The next phase of dissection includes the division of the short gastric arteries, and posterior mobilization of the stomach. The light cord of the laparoscope is rotated 30 degrees counterclockwise (11 o'clock position), and the surgeon grasps the greater curvature of the stomach at the level of the inferior pole of the spleen. The assistant grabs the greater omentum adjacent to the greater curvature of the stomach. The surgeon retracts the stomach to the patient's right and posteriorly while the assistant elevates the omentum anteriorly and to the patient's left. The ultrasonic shears are introduced and entry to the lesser sac is gained by incising the greater omentum adjacent to the greater curvature of the stomach (Fig. 16.4). Several applications of the harmonic scalpel may be necessary to gain access to the lesser sac in heavier patients. It is important that the short gastric vessels are visualized and completely occluded with the ultrasonic shears before the application of energy. Incomplete division of short gastric vessels results in troublesome bleeding. As the dissection moves cephalad, the surgeon keeps moving the retraction point higher along the greater curvature, generally placing one jaw of the atraumatic grasper on the anterior wall of the stomach and one jaw on the posterior aspect of the stomach. The assistant places one jaw of their grasper in the lesser sac, and one jaw in the greater sac to optimally retract the greater omentum.

When one approaches the superior pole of the spleen, a different retraction strategy is required. Incision of the peritoneum at the superior pole of the spleen widens the splenogastric omentum into several layers. To adequately expose this remote corner of the abdominal cavity, both surgeon and first assistant retract on the stomach. The surgeon grasps the fundus of the stomach on the anterior surface and the assistant grasps the fundus of the stomach on the posterior surface. The surgeon retracts anteriorly and to the right. The assistant retracts posteriorly and to the right. This opens up the field at the superior pole of the spleen. If a fatty greater omentum fills the lesser sac to the superior of the spleen, obscuring the field of dissection, it may be necessary to reef up and retract the omentum inferiorly with a 90 cm 2-0 polypropylene suture that is brought out of the abdominal wall through the trocar in the left anterior axillary line. One should not proceed with dissection of this area without adequate exposure of the anterior wall of the stomach, the posterior wall of the stomach, and the superior pole of the spleen. Generally, the light cord...
of the laparoscope is rotated back to the 12 o'clock position or to the 1 o'clock position to visualize this region.

The next point of dissection is the posterior pancreaticogastric fold, which contains the posterior gastric artery. This fold is identified by medial retraction on the posterior body of the stomach, lower on the stomach than was necessary to expose the tip of the spleen. Medial and occasionally anterior retraction of this posterior wall lifts the posterior stomach away from the posterior retroperitoneum, exposing a consistent band from the superior surface of the pancreas (near the splenic artery) to the posterior aspect of the stomach (Fig. 16.5). This band is divided with the harmonic scalpel, moving in a cephalad direction toward the base of the left crus of the diaphragm. The posterior gastric artery encountered in this bundle is taken with the ultrasonic shears. When the base of the left diaphragmatic crus is reached, dissection then proceeds anteriorly along the left crus of the diaphragm dividing all attachments between the left crus and the gastroesophageal (GE) junction. At this point, the posterior vagus nerve becomes visible from either the left or the right side of the esophagus, lying adjacent to the posterior esophagus.

A Penrose drain is placed around the GE junction. For most dissections, a 4 cm length of ¾ inch Penrose drain is appropriate. The two ends of the drain are held by the assistant anteriorly while the surgeon places an endo loop on the drain to hold the ends together. The assistant then replaces the atraumatic grasper with a more aggressive grasper, which can be ratcheted down and retracts the GE junction caudally and slightly to the patient’s left. This allows access to the mediastinum on the right side of the esophagus. The surgeon mobilizes the distal esophagus from the posterior mediastinum with a combination of blunt dissection and ultrasonic shears. Most periesophageal attachments can be divided bluntly between two graspers without risking thermal injury to either vagus nerve.

The extent of mediastinal dissection varies as the only requirement is to achieve a tension-free intra-abdominal esophageal length of 3 cm. The best way to assess tension-free intra-abdominal length is to remove the assistant’s grasper from the Penrose drain and perform a trial closure of the diaphragm posteriorly with two graspers. A dissecting instrument or ruler may be used to measure the length of esophagus remaining below the diaphragm at rest.

Once it has been determined that there is adequate length of intra-abdominal esophagus, attention is directed toward closure of the diaphragmatic hiatus with nonabsorbable braided suture on an atraumatic round needle. Sutures are placed 5 to
10 mm apart, require deep bites of the left and right crura of the diaphragm, and are tied intracorporally. Because crural failure has been noted in many fundoplication procedures, we use 1 cm square Teflon-felt pledgets to buttress the closure (Fig. 16.6).

Upon completion of the crural closure, an atraumatic grasper is placed from right to left behind the GE junction, and the posterior aspect of the gastric fundus is grasped and pulled behind the esophagus. To avoid twisting the wrap, it is important that the posterior wall is the portion grasped. The posterior wall is then walked hand-over-hand backwards down toward the angle of His to make sure that a point high on the fundus has been chosen. A "shoe-shine" maneuver is performed by sliding the two proposed points of fixation back and forth behind the esophagus (Fig. 16.7).

At this point, the orogastric tube is removed and a large Maloney dilator (54F to 60F) is passed into the stomach. This maneuver has been associated with esophageal perforation in 0.5% to 1.0% of operations but may be preventable if several measures are taken. First, close communication between the anesthetist and surgeon is mandatory. The anesthetist should alert the surgeon to the distance of the tip of the dilator from the incisors marked on the side of the dilator. In addition, we pass a small dilator (36F to 40F) first to insure that there is unobstructed passage into the stomach. While smaller dilators tend to fold back on themselves before perforating the esophagus, larger dilators more commonly will perforate if they run into an irregular stricture or diverticulum. Equally important, the inferior traction on the Penrose drain must be released and the laparoscope pulled back as the tip of the dilator passes into the stomach.

Once the dilator has been placed, a fundoplication is fashioned. The position for the first stitch is chosen by pulling the two limbs of the fundus together at the 10 to 11 o’clock position on the esophagus. There should be no circumferential tension on the fundus with this maneuver. If there is tension, another point on the stomach, closer to the greater curvature is chosen. Once the suture positions are chosen, the first stitch (0 Ticron, 9 cm long) is introduced through the 11 mm trocar, and the needle is passed first through the left limb of the fundus, then the esophagus (2.5 cm above the GE junction), and then through the right limb of the fundus. A slipknot is placed, and as the knot is sliding into place the two halves of the fundus are pulled into their final position. The “floppiness” of the fundoplication is tested by placing a closed grasper between the dilator and the fundoplication to the left of the esophagus, and distracting the fundoplication away from the esophagus. This maneuver should allow 1 cm worth of redundancy between the fundoplication and the esophagus (Fig. 16.8). If the fundoplication is too loose or too tight, the first stitch is removed and another is placed. Subsequent stitches should be placed no more than 1 cm apart, thus creating an anterior distance between the top and bottom of 2 cm. It is important to place the superior stitch first, and the inferior stitch last, just above the GE junction. We generally place all three esophageal sutures to the right of the anterior vagus nerve (Fig. 16.9). We place an additional suture posteriorly between the esophagus and the fundoplication to avoid posterior fundoplication slippage. The dilator is then removed and the fundoplication is placed in its anatomic position beneath the diaphragm.

The Penrose drain is removed and the small amount of blood that accumulates

Fig. 16.6. Crural closure with pledgets.

Fig. 16.7. The “shoe-shine maneuver.”
between the spleen and diaphragm is evacuated. The liver retractor and each of the trocars are removed under direct vision. We do not close the trocar sites in the upper abdomen that are 11 mm in diameter or less and have not seen hernia complications resulting. The skin is reaproximated with subcuticular sutures and tissue glue.

Laparoscopic Partial Fundoplication

Partial fundoplication is indicated in patients with preoperative dysphagia and poor esophageal motility. Types of partial fundoplication include a 270 degree posterior wrap (Toupet), a 180 degree anterior and posterior wrap to the median arcuate ligament (Hill gastroplexy). We preferentially perform a Toupet fundoplication as it is generally thought to provide superior reflux control compared with other partial fundoplications. A Dor fundoplication is used after performing a Heller myotomy due to its ability to provide coverage over an anterior myotomy. Few surgeons perform a Dor as a primary antireflux operation.

The initial steps in performing a Toupet fundoplication are similar to those for LNF. After mobilization of the esophagus, division of the short gastric vessels and closure of the crura, the tip of the fundus is brought posteriorly around the esophagus as for a total fundoplication. An esophageal dilator is placed. Using three or four interrupted 0 Ticron sutures, the anterior aspect of the wrapped portion of the stomach is sutured to the right lateral wall of the esophagus just anterior to the anterior vagus nerve. The gastric fundus is sutured to the left side of the esophagus just anterior to the posterior vagus nerve.

Gastroplasty

A Collis gastroplasty was originally described in patients suffering from esophageal shortening caused by peptic stricture with severe contraction fibrosis. It was designed to create a tube of gastric cardia with a diameter similar to that of the esophagus that permits creation of an intra-abdominal, tension-free, fundoplication around this “neoesophagus.”

The operation is performed laparoscopically during the course of LNF. After mobilization of the esophagus as high in the mediastinum as possible and closure of the crural defect, esophageal length is measured by means of an open Hunter grasper (2.5 cm). If 3 cm of intra-abdominal esophagus is not present, then a Collis gastroplasty is indicated.

A 48F Maloney dilator is passed and the gastroplasty performed with this in place. The neoesophagus is constructed by means of three firings of a 45 mm, purple or blue load, endo-GIA stapler (Covidien, Inc., Greenwich, CT). The stapler is inserted through a 12 mm port in the left subcostal area. The first firing is performed at a 90 degree angle to the dilator approximately 3 cm distal to the GE junction (Fig. 16.10). The second firing is performed in the same direction up to the dilator (Fig. 16.11). The final firing is done parallel to the dilator, and the wedge of stomach is removed from the abdomen (Fig. 16.12). The wrap is then performed as previously described for LNF.

Transthoracic Nissen Fundoplication

The advent of the laparoscopic approach to Nissen fundoplication has relegated this procedure to the realm of historical significance except for the occasional need for revision of a previous fundoplication where repeat laparoscopy, for a variety of reasons, is not feasible. The anesthesiologist places a double-lumen tube or bronchial blocker to permit single-lung ventilation and the patient is placed in the right lateral decubitus position. A lateral thoracotomy is performed and the chest is entered through the seventh intercostal space preserving the serratus anterior muscle. A 1 cm segment of the eighth rib may be taken posteriorly to allow greater rib spreading without causing a fracture. The distal esophagus is mobilized to the level of the inferior pulmonary vein taking care not to enter the right pleural space. The vagus nerves are preserved and are left on the esophagus. The phrenoesophageal membrane is divided near its insertion on the esophagus to enable entry into the peritoneal cavity through the esophageal hiatus. The esophagogastric junction is mobilized circumferentially. When the crura and the left lobe of the liver are exposed, the hiatal dissection is complete. The proximal stomach is pulled into the chest, the gastric fat pad is excised
to permit apposition of the gastric serosa to the esophagus, and several short gastric vessels are divided to provide adequate mobilization of the stomach.

Interrupted nonabsorbable sutures are placed in the crura for future hiatal repair. The first suture is placed at the initial decus- sation of the crural fibers, and subsequent stitches are placed cephalad at 1 cm intervals until an adequate closure of the hiatus is possible. This usually requires three or four sutures (Fig. 16.13). The stitches are left untied until the fundoplication wrap is completed. A large (56F to 60F) dilator is placed so that it traverses the GE junction. The tip of the fundus is grasped in the surgeon’s left hand and is brought posteriorly around the esophagus, where it is held with an atraumatic clamp. A portion of the stomach high on the body is pulled across the esophagus to meet the wrapped portion of the fundus. Three interrupted sutures are placed through the stomach to the left of the esophagus, through the muscularis of the esophagus, and again through the gastric fundus lying to the right of the esophagus. These are spaced at 1 cm intervals to create a 2 cm wrap (Fig. 16.14). After the sutures are tied, the dilator is removed, and the wrap is reduced below the diaphragm, where it should rest without tension. The crural sutures are tied to calibrate the esophageal hiatus, leaving enough room to allow the tip of one finger to be admitted easily alongside the esophagus. A nasogastric tube is placed and the chest is closed after an intercostal drain is placed.

**Transthoracic Partial Fundoplication (Belsey Mark IV)**

The initial portions of the operation are performed in a manner similar to that described for the transthoracic Nissen fundoplication, although it is usually not necessary to divide any of the short gastric vessels. Crural sutures are placed but are left untied. The partial fundoplication is begun by placing mattress sutures of interrupted nonabsorbable material through the stomach 1 cm distal to the esophagogastric junction and through the esophagus 1 cm proximal to the junction. Three sutures make up the first layer: one just anterior to the anterior vagus nerve, one just anterior to the posterior vagus nerve, and one midway between these two (Fig. 16.15). After these sutures are tied, a second row of mattress sutures is placed. These are first passed through the diaphragm, close to the margin of the central tendon. They then are placed through the stomach and esophagus in a mattress fashion, encompassing an
additional 1 cm of stomach distal to and 1 cm of esophagus proximal to the previous sutures, and finally are brought through the diaphragm again (Fig. 16.16). The wrap is reduced below the diaphragm, where it should rest without tension. The second row of sutures is then tied to create a 240 to 270 degree wrap that is anchored underneath the diaphragm. The crural sutures are tied to calibrate the esophageal hiatus, leaving sufficient room to admit the tip of one finger posteriorly alongside the esophagus (Fig. 16.17). The chest is closed after an intercostal drainage catheter is inserted.

**Postoperative Care**

Prior to emergence from anesthesia the patient is prophylactically treated for postoperative nausea with ondansetron and phenergan. A low dose of steroids may be added for their antiemetic effects. Ketorolac is administered to diminish postoperative pain. The patient is extubated and the Foley catheter is removed. No nasogastric tube is necessary for LNF. A clear liquid diet is offered in the evening of surgery and the patient is advanced to a full liquid diet by the first postoperative day. Antiemetic medications are scheduled and given on an as-needed basis to minimize the chance of retching with subsequent diaphragmatic stress. All medications are crushed or administered in a liquid form. Discharge occurs on the first postoperative day in patients who do not undergo thoracotomy. An esophagogram is obtained on the first postoperative day only after revisional anti-reflux surgery. Because of distal esophageal edema, patients are instructed to follow a full liquid diet for 5 days followed by a mechanical soft diet for 3 weeks. Specifically, they are instructed to avoid breads, meats, and raw vegetables. With strict adherence to this protocol, few patients complain of postoperative dysphagia. Without such aggressive management, food impaction, nausea, retching, and wrap disruption have been reported. Patients may resume activities of daily living immediately but avoid events involving intra-abdominal straining for 4 to 6 weeks to minimize the likelihood of acute fundoplication herniation.

**SURGICAL COMPLICATIONS**

Serious complications after LNF are rare. A large meta-analysis demonstrated a mortality rate of 0.08%, reoperation rate of 2.7%, and splenectomy rate of 0.06%. Unrecognized gastric and esophageal injuries and acute fundoplication herniation represent potentially devastating complications. The fundamental caveat in postoperative care, therefore, is that any patient who fares poorly for any reason should be studied with a barium swallow to rule out perforation or herniation. With expeditious diagnosis and urgent reoperation, the outcome in these patients is good.

Early postoperative dysphagia can occur in up to 16% of patients after LNF, but only 2.5% of patients experience dysphagia at long-term follow-up. Patients with preoperative dysphagia, even in the face of a normal esophageal manometry study, are more likely than those without to experience postoperative dysphagia. Other postfundoplication complaints include rectal flatulence and inability to belch or vomit. These complaints tend to improve over time without specific intervention.

**RESULTS OF SURGERY**

Excellent long-term outcomes after LNF have been well documented in the literature. Greater than 90% of patients can expect to have reflux control at 10 years. Seventy to 90% of patients remain off PPIs and 93% of patients would undergo LNF again. Those patients with predominant
respiratory symptoms tend to do less well than those with typical symptoms. A substantial number of patients with Barrett’s esophagus may experience regression of metaplasia and even dysplasia postoperatively. Initial success after LNF in patients with Barrett’s esophagus is equivalent to those without, but there may be more anatomic failures in this group.

**ROLE OF REVISIONAL ANTIREFLUX SURGERY**

With the dramatic increase in LNF over the last two decades, esophageal surgeons continue to see a significant number of patients with “failed fundoplications.” The definition of a failure after LNF is controversial as it can be defined in strictly anatomic terms, as resumption of PPIs, and/or may take into consideration functional outcome as determined by the patient. If failure is only defined in anatomic terms or as resumption of PPIs, then a patient with good symptom control but radiographic evidence of a small hiatal hernia would be considered a failure as would a patient with excellent reflux control with the resumption of minimal amounts of PPIs. On the other hand, if failure is defined on functional grounds then the rate of failure may increase significantly as most patients with esophageal complaints after LNF have no anatomic or physiologic abnormalities. We feel that defining failure in terms of patient symptoms is most appropriate as LNF is a functional procedure.

Up to 16% of patients will experience anatomic or physiologic failure and 3% to 6% of patients will require a revisional antireflux surgery. Those patients who experience recurrent esophageal symptoms should be evaluated with an upper gastrointestinal radiographic study, esophagogastric manometry as clinically indicated. These studies will define the nature of the symptoms and define an anatomic failure. The most common mechanism of anatomic failure is fundoplication herniation into the mediastinum. Most surgeons approach revisional antireflux operations laparoscopically, especially if the first operation was performed laparoscopically. The results of revisional surgery are very good. Success rates are approximately 80% and only 16% of patients are unsatisfied with redo LNF. Success rates decrease dramatically, however, after the first revisional surgery for a variety of reasons, many of them are functional rather than anatomic. The patient who has undergone multiple antireflux operations, therefore, should be approached with caution.

**SUGGESTED READINGS**

For patients who have continued reflux symptoms despite ideal pharmacologic management, the advent of the laparoscopic Nissen fundoplication (LNF) has made the surgical alternative significantly less foreboding. Patients may be discharged on the first postoperative day with minimal pain and able to eat a full liquid diet with rapid progression to a mechanical soft diet. Both the short- and long-term results of the procedure have been excellent in terms of elimination of reflux symptoms. Interestingly, there seems to be significant variation in the number of these cases performed based on geographic areas. It seems that in certain locations the gastroenterologists seem much more willing to refer cases for operation as compared with other areas where they are extremely hesitant about referring a patient.

The key to success with LNF is patient selection just as it is with other operations designed to alleviate a functional problem. Patients should have a complete preoperative evaluation that includes a pH study, ideally over a 24-hour duration, as well as esophageal manometry. Attention to technical detail is particularly important for optimal outcome and symptom relief without causing a new problem such as dysphagia where previously it did not exist. The authors have provided the pertinent technical details that should be carefully followed. Transient dysphagia may occur in some patients but it should be short lived as the edema resolves.

Rarely is there a need for an open abdominal operation for fundoplication no matter the type of wrap chosen. The thoracic approach should be reserved for those patients in whom revision is necessary and either multiple previous operations have been attempted or previous complications have occurred. A left thoracoabdominal approach may occasionally be useful to approach the left upper quadrant that has previously been violated with multiple procedures and attendant complications. Coming from the chest allows for the esophagus to be visualized, the spleen kept out of the way, and complete mobilization to be effected. The only caveat to this approach is taking care at the time of closure to accurately reapproximate the diaphragm and the costal arch.

LRK
INTRODUCTION

The technique of transhiatal esophagectomy (THE) without thoracotomy and a cervical esophago gastric anastomosis (CEGA) was rediscovered in the mid-1970s. Since then, the operation has been progressively refined and has emerged as a recognized alternative to traditional transthoracic esophagectomy for both benign and malignant disease requiring resection and reconstruction. Since the earliest reported series of transthoracic esophagectomy and an intrathoracic esophago gastric anastomosis, the leading causes of postoperative morbidity and mortality have been (1) respiratory insufficiency resulting from a combined thoracoabdominal operation and (2) mediastinitis from an intrathoracic anastomotic leak. THE addressed both issues. By eliminating a thoracic incision, postoperative pulmonary complications were less. By placing the esophagogastric anastomosis in the neck, a leak meant a mobilization of the esophagus and therefore a thoracic aorta; displacement of the megaesophagus into the right chest; larger than usual aortic esophageal arteries; and a much wider than usual esophageal hiatus, conversion to a transthoracic esophagectomy for both transthoracic esophagectomy and a CEGA is a safer option. When performing a THE, the surgeon must always be prepared to convert to a transthoracic approach when unexpected bleeding or unusually severe fixation of the esophagus to adjacent structures is encountered.

INDICATIONS AND CONTRAINDICATIONS

For most conditions for which esophageal resection and replacement are indicated, THE and a CEGA are applicable. The authors and his colleagues have reported a series of 2,007 THEs, 1,525 (76%) for carcinoma of the intrathoracic esophagus and 482 (24%) for benign disease (Table 17.1). Indications for esophagectomy in achalasia include a failed prior esophagomyotomy, a reflux stricture after a prior esophagomyotomy (often without a concomitant antireflux procedure), and a tortuous megaesophagus (>6 cm in size). Technical hazards unique to an esophagectomy for achalasia include adherence of the formerly myutomized esophagus to the adjacent descending thoracic aorta; displacement of the megaesophagus into the right chest; larger than usual aortic esophageal arteries; and a much wider than usual esophageal hiatus; conversion to a transthoracic esophagectomy for both transthoracic esophagectomy and a CEGA is a safer option. After two failed antireflux operations, the likelihood of achieving long-term reflux control and comfortable swallowing is sufficiently low that the author advocates a THE in those requiring further surgery. But this decision is not made lightly. Such patients must be informed about the potential functional “downside” of esophagectomy, including dysphagia from an anastomotic stricture, early satiety, posture-related regurgitation, and dumping symptoms. Occasional reflux or intermittent dysphagia from a recurrent hiatal hernia may be a better option than continuing with an esophageal anastomotic stricture or chronic dumping symptoms for the rest of one’s life.

In the author’s experience now with more than 3,000 THEs, this operation has been possible in 98% of patients requiring an esophageal resection for both benign and malignant disease. Contraindications to THE include documented invasion of the airway by upper or middle third esophageal cancers; histologically proven distant metastatic (M1) esophageal carcinoma; and most importantly, the surgeon’s assessment through the diaphragmatic hiatus at the time of the planned esophagectomy that tumor fixation to adjacent mediastinal structures precludes a safe transhiatal “blind” dissection. In those with a history of a prior transthoracic esophagomyotomy, adherence of the exposed submucosa to the adjacent thoracic aorta often creates a technical challenge, and if the esophagus cannot be adequately dissected away from the aorta under direct vision through the hiatus, conversion to a transthoracic esophagectomy is a safer option. When performing a THE, the surgeon must always be prepared to convert to a transthoracic approach when unexpected bleeding or unusually severe fixation of the esophagus to adjacent structures is encountered.
practice to utilize preoperative mesenteric angiography to evaluate the blood supply of the colon unless there is a history of mesenteric vascular disease or possible interruption of the inferior mesenteric artery in a prior abdominal aortic aneurysm repair. Abstinence from cigarette smoking for a minimum of 3 weeks before the operation is an absolute requirement of the author, even in those with cancer. Those suspected of continued smoking have a urine cotinine level determined, and if recent tobacco use is confirmed, the operation is cancelled. Patients are issued an incentive spirometer at the initial consultation and are requested to use it on a set schedule throughout the day until they are admitted for their operation. They are instructed to walk 3 miles a day to condition themselves for early postoperative ambulation. The importance of this "surgeon–patient contract" is emphasized. With severe esophageal obstruction and inability to obtain adequate fluid and caloric intake by mouth, a nasogastric feeding tube is placed into the stomach, if necessary with fluoroscopic control, and tube feedings for home use are initiated. Every effort is made to avoid a hospitalization and the need for intravenous hyperalimentation before surgery, and patients are typically admitted for the esophagectomy on the day of the scheduled procedure. A mechanical cleansing of the large bowel is undertaken in those in whom there is concern about the suitability of the stomach as an adequate esophageal replacement.

**SURGICAL TECHNIQUE**

The four phases of THE—abdominal, cervical, mediastinal (transhiatal), and anastomotic—are performed in a sequential and reproducible fashion from patient to patient. Placement of an epidural catheter preoperatively for both intraoperative and postoperative pain control is an important advance. Flexible esophagoscopy is performed after induction of general anesthesia to insure the availability of an adequate proximal esophageal margin as well as a healthy gastric conduit for esophageal replacement. Excessive air insufflation should be avoided. After the endoscopy, a 16F nasogastric tube is placed. A radial artery catheter for intraoperative monitoring of blood pressure during the mediastinal dissection is routine. This catheter is well-secured to avoid its dislodgment during this operation in which the arms will be at the sides, not secured to arm boards. The patient is positioned supine on the operating table with the head turned toward the right and supported on a soft head ring, and the neck extended by a small shoulder roll under the scapulae. The wrists, elbows, and arms are carefully padded with foam, placed at the sides, and secured in place with the drape sheet. This positioning allows the surgeon and his/her assistant unobstructed access to the patient’s neck, chest, and abdomen. Table-mounted brackets for securing an upper-hand retractor during the abdominal phase are positioned at the nipple line. “Bumping up” one side or another for an anterolateral thoracotomy in case a transthoracic exposure is required is not done. If conversion to a transthoracic esophagectomy is required, the abdomen is quickly closed temporarily with 4 or 5 through-and-through full-thickness #2 nylon sutures, the wound covered with a plastic surgical drape, and the patient turned and repositioned in the lateral decubitus position for a true posterolateral thoracotomy. After completion of the transthoracic esophagectomy, the chest is closed and the patient turned supine once again and positioned as before for completion of the procedure. The operative field extends from the mandible to the pubis and from one midaxillary line to the other. Two suction catheters, one at the head of the table and one from below, are used routinely. This operation is best performed from the left side of the operating table, and the following operative description of THE is how the procedure would be viewed by the surgeon so positioned.

### Abdominal Phase

The sequence of this phase of the operation is gastric mobilization, distal esophageal transhiatal mobilization, Kocher maneuver,
pyloromyotomy, and finally feeding jejunostomy. Through an upper midline supraumbilical incision (Fig. 17.1, inset), the abdomen is explored, the triangular ligation of the liver divided with electrocautery, and the left lobe of the liver retracted to the right with a liver blade retractor secured to the upper-hand supporting bar. A standard upper-hand abdominal wall retractor secured to the bar is used to retract the left side of the abdominal wall. The high greater curvature of the stomach is localized, and the adjacent greater omentum retracted to the left. A “clear space” between the omentum and the gastric wall is developed until the lesser peritoneal sac is entered. An index finger passed into this opening behind the greater omentum elevates the omentum away from the stomach and is used to define the high short gastric vessels and left gastroepiploic arcade. These vessels are sequentially clamped with 13-inch long right-angle clamps, divided, and tied with 2-0 silk, taking care to stay well away from the stomach to avoid ischemic necrosis. The gastric wall must be handled gently throughout this mobilization and unnecessary traction on the stomach avoided. Care must also be taken to avoid excessive downward traction on the high greater omentum that may be adherent to the spleen and result in a splenic capsular tear. Before dividing all of the high short gastric vessels, the direction of the dissection is changed, and the remaining left gastroepiploic vessels sequentially identified, clamped, divided, and ligated moving along the greater curvature toward the pylorus.

The right gastroepiploic artery is identified by palpation and vision as it either terminates in the gastric wall or communicates through fine vessels with the left gastroepiploic arcade. The greater omentum is divided 1.5 to 2 cm inferior to the right gastroepiploic artery, carefully preserving it and repeatedly monitoring for the presence of a pulse before dividing and ligating each branch. The greater omentum is separated from the stomach to the level of the pylorus. Once this portion of the distal stomach has been mobilized, it can be better retracted to the right exposing the highest short gastric vessels still to be divided. The peritoneum overlying the hiatus is incised and the esophagogastric junction identified. The author no longer encircles the esophagogastric junction with a Penrose drain in order to minimize the chance of a traction injury to the upper stomach. The stomach is elevated and any adhesions between the retroperitoneum and posterior gastric wall divided with electrocautery.

Attention now shifts to the lesser curvature of the stomach. One hand is passed behind the mobilized greater curvature of the stomach into the lesser peritoneal sac until the fingers can be seen through the filmy gastrohepatic omentum on the lesser curvature side of the stomach. The gastrohepatic omentum is incised with electrocautery progressing superiorly toward the diaphragmatic hiatus, carefully palpating for a pulse in an aberrant left hepatic artery arising from the left gastric artery. This aberrant vessel is preserved if present by dividing the left gastric artery distal to its origin. By retracting the stomach to the left, the lesser curvature soft tissues are tensed, facilitating identification, mobilization, clamping, dividing, and ligating of the left gastric vein and then the left gastric artery with 2-0 silk ties. The artery is doubly ligated at its origin from the celiac trunk, and all lymph nodes in this area dissected and swept to the left attached to the lesser curvature. Similarly, all soft tissue and lymph nodes along the lesser curvature of the stomach anterior to the right crus of the diaphragmatic hiatus are swept to the left with the stomach. With mobilization of the greater curvature and high lesser curvature of the stomach completed, dissection of the esophagogastric junction and lower esophagus is begun.

The mobilized stomach is gently retracted downward as the phrenoesophageal tissue at the level of the hiatus is incised and the posterior mediastinum entered anterior to the esophagus. This space is enlarged bluntly with a sweeping...
motion of the fingers so that a narrow heart-shaped retractor can be inserted and upward traction on it exerted. This exposes the distal esophagus in the posterior mediastinum. If tumor at the cardia is adherent to the diaphragm, a rim of diaphragm may need to be resected with the specimen to achieve an adequate margin. The posterior aspect of the esophagus is gently mobilized away from the spine by two, three, and then four fingers inserted into the hiatus behind the esophagus. Using a long 13-inch right-angle clamp and a long electrocautery tip, the posterior mediastinal paraesophageal soft tissues are elevated and divided. Visible paraesophageal lymph nodes are resected. The dissection alternates from one side to the other of the esophagus moving progressively toward the carina. If either lung is seen in the field, the mediastinal pleura on that side has been violated, and a chest tube will be required later. Inserting a hand into the low mediastinum and gently “rocking” the esophagus from side to side allows assessment of the degree of fixation between the esophagus and contiguous structures, particularly the spine, prevertebral fascia, and descending thoracic aorta, which could complicate transhiatal esophageal dissection. During this low esophageal dissection, blood pressure as recorded through the radial artery catheter is carefully watched to avoid prolonged hypotension resulting from cardiac displacement by the hand inserted into the mediastinum. After mobilizing approximately 10 cm of the distal esophagus, the low posterior mediastinum is packed with a large abdominal pad to facilitate hemostasis.

The duodenum is mobilized with a generous Kocher maneuver to facilitate the eventual upward reach of the stomach through the posterior mediastinum. After an adequate Kocher maneuver, the pylorus should be able to be grasped and moved from its usual position in the right upper quadrant to the level of the xiphoid process. A pyloromyotomy is now performed. Two 3-0 silk figure-of-eight traction sutures are placed, one through the superior aspect and the other through the inferior aspect of the pylorus. The anterior pylorus is thus elevated as the pyloromyotomy is begun. Using a low cutting current from a needle-tipped electrocautery, the gastric serosa and superficial muscle layers are incised beginning approximately 1.5 to 2 cm on the gastric side of the pylorus. A fine right-angle clamp is then used to elevate the remainder of the muscle away from the submucosa as the muscle is progressively divided moving toward the pylorus. The dissection then becomes more superficial as the serosa and a few muscle fibers underlying the pylorus and cut, and the serosa and muscle of the duodenum divided for 0.5 to 1 cm. The duodenal submucosa is distinctly different from the gastric submucosa, the former being more fatty, more yellow in color, and having fine veins coursing over it, while the gastric submucosa is more pink and has relatively fewer veins on its surface. With the gastric and duodenal submucosa exposed on either side of the pylorus, the pyloric muscle is readily identified, dissected, and elevated with the right-angle clamp, and progressively divided with the needle-tipped electrocautery. Freely bulging submucosa between the two cut ends of the pylorus signifies a complete myotomy. At the conclusion of the pyloromyotomy, a silver hemoclip is placed near the pylorus at the base of either traction suture to mark the level of the pylorus for future radiographic evaluation. Should the integrity of the pyloroduodenal mucosa be violated, the pyloromyotomy is not converted to a pyloroplasty. Rather, the hole is closed with several interrupted 5-0 polypropylene sutures. This avoids a pyloroplasty suture line at right angles to the vertical axis of the stomach when the stomach is pulled upward through the posterior mediastinum. If repair of a pyloroduodenal mucosal tear is required, once the stomach has been brought through the mediastinum and the fundus delivered to the neck, the pyloromyotomy site, which typically comes to rest approximately 3 to 4 cm below the level of the hiatus, is buttressed with adjacent omentum or greater curvature fat loosely “tacked” in place with several interrupted 4-0 sutures. A feeding jejunostomy is performed using a 14F rubber catheter with side holes cut at its tip inserted into the bowel 18 to 20 cm distal to the ligament of Treitz. The tube is secured in place with a 4-cm long Witzel maneuver. The jejunostomy tube is not yet brought through the abdominal wall but rather covered with a towel clamped on either side to the drapes with hemostats as it emerges from the lower end of the abdominal incision to prevent its dislodgment during the remainder of the operation. Attention is now turned toward the neck.

Cervical Phase

Palpation of the cricoid cartilage identifies the level of the cricopharyngeus sphincter, the esophageal introitus. A 5 to 7 cm long oblique left cervical incision that parallels the anterior border of the sternocleidomastoid muscle is made (Fig. 17.2). The incision extends no more than 2 cm superior to the cricoid cartilage, as there is no esophagus above this point, a long cervical incision toward the angle of the mandible contributes nothing to exposure of the esophagus. The incision is deepened through the platysma muscle and then the fascia along the anterior edge of the sternocleidomastoid muscle. The sternocleidomastoid muscle is separated from the underlying cervical muscle using blunt finger dissection in the direction of the muscle. The sternocleidomastoid muscle is retracted laterally, and the underlying omohyoid muscle can be seen coursing obliquely in the opposite direction of the sternocleidomastoid muscle. The tendinous midpoint of the muscle is elevated with a fine right-angle clamp and divided with electrocautery (Fig. 17.3). Traction on the cut medial side of the omohyoid muscle tenses the omohyoid fascial layer, which is incised with electrocautery in the direction of the cervical incision. This omohyoid fascial layer leads to the underlying carotid sheath and its contents. Throughout the entire cervical portions of this operation, no metal retractors are placed against the tracheoesophageal groove in order to avoid injury.
Fig. 17.3. The left sternocleidomastoid muscle is retracted laterally revealing the underlying omohyoid muscle, the central tendon of which is elevated with a right-angle clamp and divided with electrocautery. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

to the recurrent laryngeal nerve. While the sternocleidomastoid muscle and carotid sheath are retracted laterally, the thyroid and trachea are retracted medially by the index finger of the first assistant (Fig. 17.4). The middle thyroid vein arises from the medial aspect of the internal jugular vein and is clamped, divided, and ligated. A critical landmark in dissection of the cervical esophagus is the inferior thyroid artery, which consistently can be found at the level of the cricoid cartilage. This artery is clamped with fine right-angle clamps, divided, and ligated. The cricopharyngeal sphincter is found immediately at the level of the inferior thyroid artery, and all subsequent dissection of the esophagus should be inferior to this point. The deep cervical fascia anterior to the prevertebral fascia is incised in the direction of the incision, and again by blunt finger dissection in the same direction, the prevertebral fascia is cleared of tissue anterior to it and the cervical esophagus (with its contained nasogastric tube) clearly identified. By following the prevertebral fascia by blunt finger dissection into the superior mediastinum, the cervical esophagus is mobilized posteriorly. The trachea and esophagus are retracted medially, tensing the left cervical strap muscles, which are elevated with a right-angle clamp and divided with electrocautery to provide optimal exposure of the esophagus at the level of the thoracic inlet.

An important maneuver in mobilizing the cervical esophagus is upward traction on the tracheoesophageal groove applied at the level of the cricoid cartilage by the first assistant's index finger (Fig. 17.5). The additional length of cervical esophagus made accessible by this maneuver facilitates its subsequent mobilization. Sharp dissection posterior and lateral to the tracheoesophageal groove is performed, but the recurrent laryngeal nerve is not actively exposed or dissected. By finger dissection, the anterior wall of the cervical esophagus is freed the length of the cervical wound. The surgeon's index finger is then advanced medially and posteriorly around the esophagus until the prevertebral fascia on the right side is palpated. As the first assistant's index finger continues to elevate the cervical esophagus out of the superior mediastinum, and with the surgeon's left index finger around the esophagus palpating the prevertebral fascia, a long right-angle clamp is passed behind the esophagus along the front of the spine until its tip is felt by the left index finger. The right-angle clamp is spread with its tip against the left index finger completing the pathway around the esophagus so that the surgeon's left index finger can now be advanced until it appears in the wound coming from behind the esophagus. With the cervical esophagus now circumferentially mobilized, a 1-inch rubber drain is placed around the esophagus to minimize inadvertent traction and the esophagus is protected the entire time with the left index finger to avoid injury to it (Fig. 17.6). The esophagus is mobilized out of the superior mediastinum by upward traction on the rubber drain as the volar aspects of the right index and middle fingers progressively sweep away the periesophageal soft tissue (Fig. 17.7). Once the cervical esophagus has been encircled and a 4 to 5 cm length of upper esophagus mobilized in the superior mediastinum, the cervical phase of the operation is completed.

Mediastinal (Transhiatal) Phase

As mentioned previously, the author now avoids an encircling Penrose drain around the esophagogastic junction (as shown in Fig. 17.7) to minimize inadvertent traction
Section I: General Thoracic Surgery

Recurrent laryngeal nerve

Sternocleidomastoid muscle

and trauma to the upper stomach. With one hand providing gentle downward traction on the mobilized stomach, the posterior mediastinal dissection is begun by advancing the opposite hand behind the esophagus along the prevertebral fascia. Resectability of the esophagus and any contained tumor, if present, is assessed by grasping the esophagus and "rocking" it to determine its mobility relative to adjacent tissues.

The drain around the cervical esophagus is elevated and retracted anteriorly, while a "half-sponge-on-a-stick" is inserted into the neck wound behind the esophagus and progressively advanced into the superior mediastinum along the prevertebral fascia (Fig. 17.8). The sponge is eventually felt by the fingers inserted through the abdomen and the hiatus. Generally, filmy posterior paroesophageal soft tissue is pushed aside and disrupted by the sponge-on-a-stick held against the finger tips. At all phases of the transhiatal mediastinal dissection, prolonged hypotension resulting from...
cardiac displacement is avoided by visually monitoring the radial artery blood pressure that is displayed on a monitor readily seen by both the surgeon and the anesthesiologist. After the posterior mediastinal "tunnel" has been created, a 28F Argyle Saratoga sump catheter is inserted through the cervical incision and advanced into the posterior mediastinal space both to assess bleeding and evacuate blood prior to the next phase of the dissection.

The anterior esophageal dissection is now begun through the abdomen by advancing the hand through the diaphragmatic hiatus palm downward against the anterior surface of the esophagus as the other hand gently retracts the mobilized stomach downward (Fig. 17.9). The drain around the cervical esophagus is retracted superiorly and toward the patient's left shoulder as two fingers are inserted through the cervical incision, volar aspects against the anterior surface of the esophagus, and advanced into the superior mediastinum. The hand inserted through the mediastinum from below must constantly be kept as far posterior as possible to minimize cardiac displacement, and as this anterior esophageal dissection proceeds, care must be taken to avoid injury to the pericardium as well as the posterior membranous trachea as the periesophageal attachments to the trachea are gently disrupted (Fig. 17.10).

After the posterior and anterior esophageal dissections, the resulting increased mobility of the esophagus in the mediastinum allows more of it to be elevated out of the superior mediastinum through the cervical incision. While "hooking" the left index finger around the esophagus and gently lifting it, disruption of the lateral esophageal attachments is performed by the right index finger advanced downward into the superior mediastinum (Fig. 17.11). A 5 to 8 cm segment of the upper thoracic esophagus is thereby completely circumferentially mobilized and is released and allowed to retract back down into the superior mediastinum.

A hand is now inserted through the abdomen and the diaphragmatic hiatus anterior to the esophagus and advanced upward through the mediastinum to the region of upper esophageal mobilization just achieved. The circumferentially mobilized upper thoracic esophagus is "trapped" against the spine between the index and middle fingers (Fig. 17.12), and the lateral periesophageal attachments and fine vagal fibers are avulsed by a progressive downward raking motion of the fingers held against the prevertebral fascia (Fig. 17.13). As the region of the inferior pulmonary hila is reached, the fine vagal fibers often coalesce to become more substantial vagal trunks. These are either ruptured by compression between the thumb and index finger or are "hooked" by the index finger and retracted downward where they can be seen through the diaphragmatic hiatus sufficiently to be elevated with a long right-angle clamp, and divided with a long electrocautery extension (Fig. 17.13, inset).

With mobilization of the thoracic esophagus from the posterior mediastinum completed, 3 to 4 cm of the upper thoracic
Fig. 17.10. As generally filmy attachments between the anterior wall of the esophagus and the posterior trachea are swept aside, care must be taken to avoid a posterior membranous tracheal tear. The hand inserted through the hiatus must be pushed posteriorly toward the spine to minimize cardiac displacement and hypotension. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

Fig. 17.11. After the anterior and posterior esophageal “tunnels” have been created, the esophagus is more mobile and can be elevated somewhat out of the cervical wound by the index finger of the left hand hooked around it. The index finger of the right hand sweeps the upper lateral esophageal attachments away from the esophagus, thereby creating an entirely circumferentially mobilized portion of the upper thoracic esophagus, which drops back into the superior mediastinum when the fingers are withdrawn. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

Fig. 17.12. A hand inserted through the diaphragmatic hiatus is advanced along the anterior surface of the esophagus up into the superior mediastinum. The index and middle fingers trap the circumferentially mobilized upper esophagus between them, and with a downward raking motion avulse the lateral esophageal attachments. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

Fig. 17.13. More substantial vagal branches are “hooked” by the downward moving index finger, delivered to the level of the hiatus, elevated with a long right-angle clamp, and divided with electrocautery. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

Fig. 17.14. With the entire intrathoracic esophagus now mobile, several centimeters of the upper esophagus is drawn into the cervical wound, the nasogastric tube is withdrawn until its tip is at the level of the upper esophageal sphincter, and the esophagus is divided obliquely from anterior to posterior (not transversely) with a gastrointestinal anastomosis (GIA) surgical stapler so that the anterior tip is longer than the posterior tip (Fig. 17.14). Unless precluded by existing esophageal pathology such as a very high squamocolumnar epithelial junction of Barrett mucosa or a midesophageal carcinoma, the upper esophagus is intentionally divided 3 to 4 cm longer than it appears will be needed to construct the cervical esophagogastric anastomosis.

After transecting the upper esophagus in the neck, the stomach is grasped in the abdomen, and with downward traction, the thoracic esophagus is delivered out of the posterior mediastinum through the diaphragmatic hiatus, and the stomach and attached esophagus are brought out of the abdominal wound. While it is always tempting at this point to examine and palpate the extirpated esophagus, inspection of the posterior mediastinum is now the priority. Once the thoracic esophagus has been delivered out of the posterior mediastinum, the liver blade of the upper-hand
retractor is removed and replaced with a standard body wall blade. This is because the deep retractor pulls the lesser curvature of the stomach toward the right upper quadrant, interfering with the subsequent upward reach of the stomach to the neck. The 28F Argyle Saratoga sump catheter is inserted into the posterior mediastinum through the neck wound, and with a long narrow Deaver retractor in the diaphragmatic hiatus, the mediastinum is inspected for untoward bleeding and both sides of the mediastinal pleura for entry into a pleural cavity. An occasional bleeding descending aortic esophageal artery may be encountered, clamped with a long right-angle clamp, and ligated. If either pleural cavity has been entered as indicated by a tear of the mediastinal pleura upon direct palpation of either side of the mediastinum or by seeing visible lung on one or both sides, a 28F-chest tube is placed in the appropriate side through a low interspace in the anterior axillary line, advanced to the apex, secured to the skin, and connected to underwater seal drainage. The blades of the upper-hand retractor should always be temporarily removed when chest tube placement is required, since the retraction distorts the anterior chest wall and may interfere with optimal chest tube positioning. When it has been established that there is no major mediastinal bleeding, a large abdominal pack is placed into the low posterior mediastinum through the diaphragmatic hiatus using a long packing forceps. Through the cervical incision, and protecting the tracheoesophageal groove with a finger, two narrow “thoracic packs” are placed into the upper mediastinum with a packing forceps. These packs provide pressure in the mediastinum to encourage hemostasis.

After chest tube placement and temporary packing of the mediastinum, preparation of the gastric conduit begins. Minimizing gastric trauma so that the stomach is “pink in the belly” (at the conclusion of its preparation) and “pink in the neck” (after it has been transposed through the posterior mediastinum) has become an overarching principle of the operation. The key to a successful esophagogastric anastomosis is a well-vascularized, healthy esophagus and stomach. Any technical maneuvers that can potentially harm the gastric blood supply are avoided. These include gastric traction sutures, suction devices applied to the stomach to pull it through the posterior mediastinum, aggressive “tubularization” of the stomach that excessively interrupts vital submucosal gastric collateral circulation, or suspending the mobilized stomach in the neck with sutures between the prevertebral fascia and the tip of the mobilized stomach, the point most vulnerable to ischemic necrosis.

The mobilized stomach and attached esophagus are placed upon the anterior chest, and the highest point on the greater curvature of the stomach that will reach upward to the neck identified and grasped with a moist gauze. At approximately the level of the second vascular arcade (“crow’s foot”) along the lesser curvature, fatty tissue and vessels are mobilized, clamped, divided, and tied to clean an area for application of the stapler. With constant gentle upward traction being applied to the tip of the stomach, and beginning on the lesser curvature of the stomach, the GIA 60-3.5 staple is applied approximately 4 to 6 cm distal to the esophagogastric junction (Fig. 17.15). The stomach is progressively straightened with each successive application of the stapler, thereby gradually eliminating the natural curve of the stomach toward the patient’s right side and achieving maximal upward gastric length. The emphasis is upon preserving a uniformly wide gastric conduit and resisting the tendency to angle the stapler toward the greater curvature and create a narrow gastric tip. Once the esophagus and proximal stomach have been separated from the gastric conduit, the specimen is removed from the field and inspected on the back table for adequacy of the gastric margin beyond tumor and of the proximal esophageal margin relative to the esophageal pathology. Frozen sections on the resected specimen may be obtained if there is concern about the margin; however, this is not done routinely.

While applying upward traction on the stomach to avoid “purse-stringing” the lesser curvature, the gastric staple suture line is oversewn from either end with two running 4-0 absorbable polyglycolic acid sutures interrupted in the mid portion of the lesser curvature to reduce the chance that the suture will break as the stomach is later drawn through the mediastinum and the tip into the neck. With preparation of the gastroesophageal conduit completed, placement of the stomach on the anterior chest shows that the stomach will reach above the level of the suprasternal notch; an additional 2 to 3 cm of length will be gained when the stomach is brought through

Fig. 17.15. With steady gentle cephalad traction on the tip of the greater curvature that will reach most superiorly to the neck, the GIA staple is applied beginning on the lesser curvature at the level of the second vascular arcade (“crow’s foot”) 4 to 5 cm distal to the esophagogastric junction. With each progressive application of the staple, the stomach is “straightened” to achieve maximum length. The maximum width of the stomach is preserved to assure the optimal submucosal gastric collateral circulation as is possible. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)
the posterior mediastinum. The gastric staple line is toward the patient’s right side (Fig. 17.16). The stomach is now lowered and brought out of the inferior end of the abdominal incision and gently wrapped in an abdominal lap pad that is moistened with warm saline.

The previously placed cervical and posterior mediastinal gauze packs are removed, and with a narrow Deaver retractor in the diaphragmatic hiatus, a final inspection for hemostasis is made. The hand and forearm are passed upward through the posterior mediastinum and advanced to the thoracic inlet to be certain that there are no major remaining adhesions, pleural bands, or vagal branches to impede the upward mobilization of the stomach. The left upper quadrant abdominal contents are retracted to the left, and the liver to the right. The wet pack around the stomach is removed and the gastric tip is “wet down” with warm saline so that it will slide more easily. As the Deaver retractor holds the hiatus open, one hand gently pushes the tip of the stomach posteriorly through the posterior mediastinum against the spine, beneath the aortic arch, and upward toward the thoracic inlet. A Babcock clamp inserted downward through the cervical incision is used to grasp the tip of the stomach held in place against the spine by the hand in the mediastinum (Fig. 17.17). To avoid unnecessary gastric tip trauma, the clamp is not ratcheted closed but rather is used to gently pull the stomach toward the neck as the hand in the mediastinum pushes the stomach upward. This continues until 4 to 5 cm of stomach comes to rest above the level of the clavicles, the stomach being pushed more from below than pulled upward from the neck wound. Proper orientation of the stomach within the posterior mediastinum should be documented by visualization in the neck of the gastric staple suture line toward the patient’s right side and demonstration of the right gastroepiploic vascular arcade at the level of the diaphragmatic hiatus toward the patient’s left side. Finally, insure that no twist in the stomach has occurred by gentle palpation of the anterior surface of the transposed stomach by one hand inserted through the hiatus and a finger inserted downward through the neck incision along the anterior surface of the upper stomach. Once in the neck, the tip of the stomach will generally remain in the wound without the need for traction sutures. Should it begin to slip back downward into the mediastinum, a moistened narrow thoracic pack placed gently behind the stomach at the thoracic inlet will usually stop the retraction. The author typically applies a hemostat across the stump of one of the ligated high short gastric vessels. As the abdominal portion of the procedure is completed, periodic confirmation that the clamp protruding from the neck is in place insures that the stomach remains in the neck wound. The cervical wound is covered with a saline-soaked gauze pack as attention is redirected to the abdomen.

The diaphragmatic hiatus has been enlarged, and occasionally partially torn, as the surgeon’s hand and forearm were inserted through it into the posterior mediastinum during the esophageal mobilization. Herniation of intestine into the chest alongside the stomach may occur unless the hiatus is at least somewhat repaired. This is generally achieved with one or two figure-of-eight #1 silk sutures placed through the hiatus to the left of the stomach. Great care must be taken to protect the right gastroepiploic vascular arcade, the pericardium and the lung as the hiatus is being narrowed. The author typically narrows the hiatus so that it will accommodate three fingers alongside the stomach within the hiatus. It is best to err on the side of keeping the hiatus loose, as excessive narrowing may result in subsequent outlet obstruction of the intrathoracic stomach. The edge of the diaphragmatic hiatus is sutured to the anterior gastric wall at the level of the hiatus with one or two 3-0 silk sutures to further prevent herniation through the hiatus. The left lobe of the liver is returned to its normal location, and an additional 3-0 silk suture is used to tack the previously divided triangular ligament back against the left side of the hiatus. The pyloromyotomy site typically comes to rest 3 to 4 cm below the level of the hiatus, covered by the overlying left lobe of the liver. The left upper quadrant, particularly the spleen, is inspected for bleeding. The feeding jejunostomy tube is brought through the abdominal wall through a stab wound in the left upper wall. The jejunostomy tube site is secured against the anterior abdominal wall with four sutures between the intestine and the adjacent peritoneum. Prior
Fig. 17.17. The stomach is gently pushed upward through the hiatus and into the mediastinum between the volar aspects of the fingers in front and the spine behind and advanced beneath the carina and the aortic arch until the tip can be felt with a Babcock clamp inserted downward through the cervical incision into the superior mediastinum. The gastric tip is grasped with the Babcock clamp, which is not ratcheted closed, and is gradually drawn into the cervical wound (inset) more by pushing from below than pulling from above. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

to cutting these sutures, each is marked with a hemoclip adjacent to the knot. This provides a “target” for the interventional radiologists should percutaneous reinsertion of a feeding tube ever be needed in the future. The jejunostomy tube is sutured to the skin. As the latter final steps are being undertaken prior to closure of the abdomen, the color of the gastric tip in the cervical wound is periodically assessed to be certain that overaggressive narrowing of the hiatus has not resulted in venous congestion that would merit removal of a hiatal suture prior to closing the abdomen. The abdominal incision is then closed and covered with a sterile towel and then a separate drape to isolate the wound from contamination by oral bacteria that may occur once the esophagus is opened in the neck for construction of the anastomosis.

Cervical Esophagogastric Anastomosis

With adequate gastric mobilization, there typically is a 4 to 5 centimeter length of stomach visible above the level of the clavicles. As was established when the stomach was brought to the neck, the gastric staple suture line is oriented toward the patient’s right side (Fig. 17.18A). The gastric staple suture line is displaced even further toward the right with a gently applied Babcock clamp to provide an area for construction of the anastomosis well away from the suture line. The anterior gastric wall is elevated somewhat with the Babcock clamp applied as low as possible behind the sternal notch, and a 3-0 silk seromuscular traction suture is placed inferior to the clamp (Fig. 17.18B). This is the first of three key sutures used to align the posterior wall of the divided cervical esophagus with the anterior wall of the stomach in preparation for the side-to-side stapled CEGA. The stapled end of the divided cervical esophagus is grasped with two Allis clamps and retracted toward the patient’s right as the gastric traction suture is being placed.

Estimating the appropriate site for the anterior gastrotomy and the length of the cervical esophagus proximal to the anastomosis may be challenging. A 1.5 to 2 cm vertical anterior gastrotomy is created after carefully assessing where the divided end of the esophagus will come to rest once the stapled end has been transected (Fig. 17.19). This is typically done with a needle tip electrocautery on a low cutting setting. The gastrotomy must be positioned sufficiently low on the anterior gastric wall that an ENDO 45-3.5 staple cartridge eventually can be inserted to its length. The stapled end of the divided cervical esophagus is grasped from front to back with a DeBakey forceps, and the staple line is amputated sharply distal to the forceps (Fig. 17.20). This amputated end serves as the “proximal cervical esophageal margin.” If there is any concern about proximity to tumor or to Barrett mucosa, the end can be submitted for frozen section analysis, but this is not done routinely. The second key suture used to set up the anastomosis is a 3-0 silk suture placed full thickness through the anterior corner of the divided cervical esophagus. The final and third stitch passes into the stomach and out 5 to 6 mm from
Fig. 17.19. With the gastric traction suture elevating the anterior gastric wall out of the depths of the incision to the level of the skin, the site of the anastomosis is selected by carefully estimating the length of the remaining esophagus and approximately where it will rest once the traction suture is removed and the stomach allowed to drop back into the wound. A 1.5-cm long vertical gastrotomy (dotted line) is made using the electrocautery cutting current. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

Fig. 17.20. The stapled end of the divided upper esophagus is grasped with two Allis clamps, a DeBakey forceps applied, and the stapled end amputated sharply just distal to the forceps in the same oblique plane in which the stapler was originally applied (anterior tip longer than the posterior). (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

the upper end of the anterior gastrotomy and then through the posterior corner of the divided cervical esophagus 7 to 8 mm from the edge and emerging 2 to 3 mm from the mucosal edge (Fig. 17.21). Care must be taken to transfix the esophageal mucosa with this latter stitch. Retracting these two latter sutures inferiorly approximates the back wall of the cervical esophagus and the anterior gastric wall. As this traction is maintained, an Endo-GIA 45-3.5 stapler (Covidien, Mansfield, MA) is inserted with the thinner anvil in the stomach and the thicker staple cartridge in the esophagus (Fig. 17.22). The stapler is gently rotated until it is pointed at the patient’s right ear and the esophagus and anterior gastric wall are aligned (Fig. 17.22A, 17.22B). It is important that the gastric staple suture line continue its orientation toward the patient’s right side, so that when the anastomotic stapler is fired, the gastric staple line is not transected, setting the stage for local ischemic necrosis.

The stapler is closed but not fired. Two “suspension sutures” of 4-0 absorbable suture, intended to minimize tension on the anastomosis, are placed on either side between the esophagus and the stomach (Fig. 17.23). The stapler is fired, thereby approximating the back wall of the esophagus and the anterior wall of the stomach and dividing the common wall between them. The stapler is removed from the field. A 16F nasogastric tube inserted by the anesthesiologist is guided by the surgeon’s finger and advanced into the intrathoracic stomach. A 4-0 absorbable suture is placed at either corner of the opened gastrotomy and esophagotomy (Fig. 17.24). Anterior closure of the esophagotomy and gastrotomy is carried out with a running full-thickness 4-0 PDS suture on the inner layer (Fig. 17.25) and inverting interrupted 4-0 PDS sutures on the outer layer (Fig. 17.26). Either side of the anastomosis is marked with a hemoclip for future radiographic evaluation. The anterior gastric wall traction suture is removed and the stomach gently “seated” in the thoracic inlet. The cervical wound is irrigated and closed loosely over a 0.25-inch rubber drain placed near the anastomosis. No more than four or five interrupted 4-0 absorbable sutures are used to approximate the cervical muscle fascia. The skin edges are approximated with running 4-0 nylon sutures. All incisions and tube sites are dressed, and the nasogastric tube is irrigated to be certain that it is functioning properly. Prior to the patient being extubated, a portable chest radiograph obtained in the operating room verifies full expansion of the lungs, no unexpected hemothorax or pneumothorax, and proper placement of the chest tube(s).

RESULTS

The Thoracic Surgery Service at the University of Michigan Medical Center has now performed more than 3,000 THEs...
Fig. 17.21. The remaining two critical sutures needed to "set up" the anastomosis are placed. The first is a full-thickness stitch through the anterior corner of the divided esophagus. The second passes into the stomach and emerges 5 to 6 mm from the upper corner of the gastrostomy. It then passes into the posterior corner of the divided esophagus 7 to 8 mm from the divided edge and traverses the wall of the esophagus obliquely, emerging 2 to 3 mm from the mucosal edge. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

Fig. 17.22. Downward traction on the two latter sutures is maintained as an Endo-GIA 45-3.5 staple cartridge is inserted into both the esophagus and the stomach, the anvil into the stomach, and the staple-containing cartridge into the esophagus. (A, B) The cartridge is gently rotated outward so that its tip gradually comes to point toward the patient's right ear, aligning the posterior wall of the esophagus with the anterior wall of the stomach. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

since 1976. In our 2007 report on over 2,000 patients, approximately 75% of these operations were for carcinoma and 25% for benign disease. As the population has aged, more octogenarians and even nonagenarians have undergone THEs. 24% of our patients being 71 years of age or older, and 5% 80 years or older. The concern expressed after our early reports on the operation that the stomach would not reliably reach to the neck has proven to be unfounded. When the otherwise normal stomach is properly mobilized, the fundus will always reach to the neck for construction of a cervical esophagogastric anastomosis. In 97% of our THEs, esophageal replacement has been achieved using the stomach as described in this chapter. In those with a history of prior gastric ulcer disease, a gastric resection, caustic gastric injury, or tumor involvement of the stomach, a long-segment colonic interposition has been used to reestablish alimentary continuity after the THE.

There were four intraoperative deaths (<1%) from uncontrollable bleeding. Entry into one or both pleural cavities during a THE is common and occurred in 75% of our patients. It was diagnosed by inspection and palpation of the mediastinal pleura through the diaphragmatic hiatus and treated with a 28F chest tube(s) as indicated. Other intraoperative complications included splenic injury necessitating a splenectomy (3%), posterior membranous tracheal tear (<1%), and violation of pyloroduodenal integrity during performance of the pyloromyotomy (<2%). This latter complication was not managed by converting to a pyloroplasty but rather by closure with several interrupted 5-0 polypropylene sutures and buttressing the area with adjacent omentum. Early postoperative mediastinal bleeding requiring a return to the operating room for control occurred in <1%. Recurrent laryngeal nerve injury is avoidable if no metal retractor is placed against the tracheoesophageal groove during the cervical portions of the operation and occurred in 1% to 2% of our last 1,000 patients. Attesting to the merit of avoiding combined thoracic and abdominal incisions in patients undergoing an esophagectomy, and improved preoperative preparation by requiring regular use of an incentive inspirrometer, walking, and cessation of cigarette smoking for several weeks before the operation, <2% have experienced sufficiently severe pneumonia or atelectasis to prolong their hospital stay. Chylothorax from thoracic duct injury occurred in <1% and was never fatal due to our very aggressive policy of early localization of the leak and thoracic duct ligation. Since adoption of the side-to-side stapled CEGA, our anastomotic
Prior to firing the stapler, two interrupted 4-0 absorbable (Vicryl) sutures between the esophagus and the stomach are placed on either side adjacent to the stapler, essentially a "second layer" of sutures. These "suspension" sutures hold the stomach in the neck wound while taking tension off of the anastomosis. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

The leak rate has fallen from 13% in our first 1,000 THEs to 9% in the second 1,000, to 3% in the author’s hands. The hospital mortality for THE in our last 1,000 patients assessed was 1%, and 71% experienced no postoperative complications.

The functional results of esophageal substitution with stomach as assessed by the presence and degree of dysphagia, regurgitation, and postvagotomy dumping indicate that 76% had a good result or excellent result, 20% required an occasional anastomotic dilatation or antidiarrheal medication (fair result), and 4% required ongoing dilatations or other treatment (poor result). Overall patient satisfaction with the ability to eat has been >95%. The overall 5-year survival for our cancer patients was 29% and was significantly better for adenocarcinoma, now being diagnosed at earlier stages. In patients 75 years of age or younger with stage II and III esophageal cancer, neoadjuvant chemotherapy and radiation therapy followed by esophagectomy have become our standard treatment. Among our patients who have been complete responders (tumors rendered T0N0 after chemoradiation therapy), 5-year survival was 58% compared with 22% in all others with any residual tumor.

**POSTOPERATIVE MANAGEMENT**

With an average blood loss with THE of under 300 ml, perioperative blood transfusions are uncommon. The importance of careful preoperative assessment and physical conditioning cannot be overemphasized: complete abstinence from cigarette smoking for at least 3 weeks, regular use of an incentive inspirometer issued at the initial office consultation, and walking 3 miles a day. This regimen translates directly to fewer postoperative complications. Fewer than 4% of our THE patients ever require postoperative intensive care. They go directly to our general care thoracic surgery unit from the recovery room, start using their incentive inspirometer the afternoon of surgery, and are out of bed walking the next day. Extubation of the patient in the operating room is routine, and epidural anesthesia facilitates pulmonary hygiene and early ambulation. The nasogastric tube is typically removed on postoperative day 3, when sips of liquids are begun. Diet is progressed each day as tolerated from clear liquids, to full liquids, to a mechanical soft, and finally a soft diet. A postoperative barium swallow is obtained on day 7, and if this shows no anastomotic leak, satisfactory emptying of the intrathoracic stomach, and no obstruction to the flow of barium past the jejunostomy tube site, the patient is discharged. Tapered Maloney esophageal dilators should be part of the esophageal surgeon’s armamentarium. Should a CEGA leak occur, it is managed by opening the neck wound at the bedside and initiating wound packing while providing nourishment through the jejunostomy feeding tube. 36, 40, and 46 French Maloney dilators are passed through the anastomosis within 1 week of opening the neck wound both to facilitate healing of the fistula by insuring free passage of swallowed esophageal contents into the stomach and to prevent the development of a late severe anastomotic stricture.
Chapter 17: Transhiatal Esophagectomy

171

Fig. 17.25. A 16F nasogastric tube is introduced by the anesthesiologist and advanced across the anastomosis by the surgeon and positioned so that the 40 cm mark on the tube is aligned with the nostril. The first row of the closure of the gastrotomy and esophagotomy is achieved with a running full-thickness row of 4-0 PDS sutures. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)

COMMENTARY

THE and a CEGA is now a well-established and efficient treatment for patients requiring an esophagectomy and esophageal reconstruction both for benign and malignant disease. In the 1970s, when the author first advocated wider use of this “less invasive” type of esophagectomy, considerable controversy was generated. Similarly, the current proponents of minimally invasive esophagectomy (MIE) must respond to those who criticize their new approach. The principles of a successful THE and CEGA, as discussed in this chapter, include (1) maximum preservation of submucosal gastric collateral circulation by preparation of as wide a gastric tube as is possible consistent with a reasonable oncologic margin, generally 4 to 5 cm distal to the esophagogastric junction; (2) progressive “straightening” and upward traction on the stomach as the stapler is applied along the curvature to achieve maximum length; (3) a generous Kocher maneuver to help achieve the maximum upward reach of the stomach that is possible; (4) a gastric drainage procedure (pyloromyotomy) to avoid postvagotomy pyloric outlet obstruction; (5) compulsive avoidance of any trauma to the gastric tip that will be used for the anastomosis; (6) direct and deliberate enlargement of the posterior mediastinal tunnel after extraction of the esophagus by the hand and forearm advanced through the hiatus to ensure that there are no remaining fibrous or neural bands to impede the transposition of the stomach through the posterior mediastinum; and (7) construction of a cervical esophagogastric anastomosis to avoid the consequences of mediastinitis associated with an intrathoracic esophagogastric anastomotic leak. In contrast, with an MIE “tubularization” of the stomach to 3 to 4 cm is advocated to facilitate passage of the gastric conduit through the posterior mediastinum that is not directly enlarged by the hand and forearm; torsion of the gastric conduit is a greater risk when the right side of the mediastinal pleura is so widely opened; a Kocher maneuver, difficult laparoscopically, is often omitted; the same applies to a gastric drainage procedure, for which a Botox injection or a “wait-and-see” posture are frequently advocated; “straightening” of the stomach during application of the stapler by the progressive application of traction to the gastric tip cannot be achieved to the same extent, and therefore there is potentially more tension on the anastomosis as a result; the tip of the gastric fundus is sutured to the end of the stapled stomach to draw the fundic end into the chest, thereby traumatizing the site of the pending anastomosis; and finally, because of the recognized increased CEGA leak rate after an MIE, proponents of the approach have gone “full circle,” now advocating an intrathoracic stapled anastomosis and accepting the small but definite risk of mediastinitis associated with an anastomotic leak. Time will tell if the traditional THE and CEGA as described in this chapter is as “minimally invasive” as an esophagectomy should be.

Fig. 17.26. The second layer of the closure is performed using interrupted 4-0 PDS sutures. (Reproduced from Orringer MB. Transhiatal esophagectomy without thoracotomy. Oper Tech Thorac Cardiovasc Surg 2005;10(1):63-83.)
SUGGESTED READINGS

**EDITOR’S COMMENTS**

To have Mark Orringer contribute the chapter on transhiatal esophagectomy (THE) truly is a privilege and an honor since he was the one who resurrected this procedure from obscurity, championed it, and withstood the initial outcry from its detractors who refused to believe that the esophagus could or should be removed without a thoracotomy. Derisively labeled by critics as “blind esophagectomy” Orringer showed that the resection could be done under direct visualization and, while blunt, certainly was not blind. He has also demonstrated significantly lower morbidity and mortality from the operation as compared with a combined thoracic and abdominal approach and he has continued to modify and improve the operation over the years. When concern was raised about the higher incidence of leaks from the cervical anastomosis he developed the technique utilizing the linear stapler that he describes in the chapter that has significantly reduced the incidence of leak. He recognized early on an unacceptable incidence of recurrent laryngeal nerve injury and stopped the use of any metal retractor on the trachea recommending only a finger as the instrument for retraction. I am not sure there is anyone more associated with a particular procedure than Orringer is with THE. And patients, as well as surgeons, are that much the better for it.

In answer to those who tout minimally invasive esophagectomy (MIE), I have pointed out that we have been doing a MIE for years. It is called THE and it avoids a chest incision of any kind. That said, one has to marvel at those who have developed and refined the laparoscopic–thoracoscopic approach though the results have failed to demonstrate any clear superiority over THE. The recent developments in robotic esophagectomy potentially may offer some advantages based on the superior visualization offered as well as the unique range of motion of the articulating wrists that essentially mimic and exceed what can be done with the human hand. Further refinements of the robotic procedure clearly will be forthcoming.

In the meantime, it is hard to quibble with the results that can be obtained with THE and the fact that the operation is applicable to essentially all patients including the elderly, as Orringer points out. Long-term survival, yet to be definitively determined with MIE, is as good or better than that achieved with either an Ivor–Lewis approach or a three-hole procedure. THE may be the optimal approach for those patients following multiple failed antireflux procedures. As Orringer also has shown the functional results obtained following THE are superb in the majority of patients. He also has stressed optimizing patients for operation by insisting on a preoperative regimen that mandates smoking cessation for at least 3 weeks prior to operation, preoperative use and training with incentive spirometry, and exercising by walking 3 miles per day. Surgeons who insist on their patients following this regimen in addition to utilizing Orringer’s technical hints, developed during the performance of over 3,000 of these operations, likely can reproduce the standard that Orringer has set for this operation. THE has more than withstood the test of time and should be a part of the armamentarium of any surgeon who wishes to venture into esophageal surgery.

LRK
INTRODUCTION

Thoracic approaches to esophagectomy may be helpful for treating benign and malignant esophageal disease. Benign indications are less common but include undilatable, recurrent strictures; mega-esophagus from achalasia, trauma, or ingestion of acids or alkali; and recurrent foregut surgery for benign processes (Table 18.1 and Fig. 18.1). More common indications include primary or salvage esophagectomy for localized esophageal cancer. Less common malignancies, such as sarcomatoid carcinoma, gastrointestinal stromal tumor, small-cell cancer, and locoregional involvement of other malignancies may also be addressed by transthoracic esophagectomy. Various thoracic approaches have been successfully used to address esophageal disorders (Table 18.2), the choice of which depends not only on surgeon preference but also on tumor location, body habitus, history of prior operations, patient condition, choice of esophageal substitute, and prior radiation therapy. A skilled esophageal surgeon does not limit the approach to a single modality but instead adopts the best approach to the individual patient. The primary goal of esophageal carcinoma treatment remains neoplasm resection, with relief of dysphagia. When selecting an approach, prior operations and conduit irradiation should be considered. In some situations such as in salvage esophagectomy, the use of a heavily irradiated conduit is unavoidable. In these cases, buttressing the esophageal anastomosis with a pedicled omental or muscle flap may be beneficial. Other challenges include previous extensive lung resections on the operated or contralateral side, which may require a left-sided thoracoabdominal approach instead of a traditional Ivor–Lewis right thoracic approach. High-risk esophageal resections can also be performed in a delayed or two-stage operation if there is concern regarding the performance of an anastomosis at the time of resection.

HISTORY

The Ivor–Lewis esophagectomy is one of the only surgical procedures named after a surgeon by first and last name and was proposed in 1946 at the Royal College of Surgeons' Humanitarian Lecture. During this era, the standard approach to mid-thoracic esophageal tumors was a transhiatal blunt esophagectomy, cervical esophagostomy, gastrostomy, and skin tube reconstruction. The original operation was described as a two-stage approach that included a laparotomy and gastric mobilization (based on the right gastric and gastroepiploic arcades), followed 1 to 2 weeks later by a right thoracotomy, with esophageal resection and esophagogastric anastomosis in the chest. Exceeding the expectations of the era, the operation was successful 70% of the time. Today, this operation is usually completed in 1 day and in one stage.

RESECTION

When esophageal resection is performed for malignant disease, the entire diseased esophagus, including any dysplasia, metaplasia, or cancer, should be removed. Recurrent cancer after a low intrathoracic anastomosis can be due to incomplete resection or recurrent disease. Adenocarcinoma can occur at multiple levels, and the seventh edition of the American Joint Committee on Cancer (AJCC) staging manual (Fig. 18.2) includes proximal gastric cancer in the esophageal cancer staging system. The management of type I and II gastroesophageal junction cancers includes extending the resection to the thoracic esophagus in order to obtain an optimum proximal margin. A gastrectomy for type III gastroesophageal junction cancers should be performed by an expert thoracic surgeon because of the potential need for simultaneous esophageal resection. Patients who are treated with definitive chemoradiation therapy and develop recurrent locoregional disease should be evaluated for a salvage esophagectomy if there is no evidence of distant disease. A transthoracic approach is favored in this situation because it allows complete resection of adjacent lymph node regions and direct placement of omental or muscle flaps to buttress these high-risk anastomoses. Palliative resection for dysphagia or bypass for tracheoesophageal fistula is seldom performed because of the availability of expandable covered stents. Patients who are at high risk for surgery can often be treated in a two-stage procedure or bypass to minimize the risks of a prolonged one-stage procedure.

PRINCIPLES OF TRANSTHORACIC ESOPHAGEAL RESECTIONS AND RECONSTRUCTION

Surgical Technique: Task List

Before the patient is brought into the operating room, the entire team should understand the operative plan. An equipment checklist will decrease intraoperative delays. All members of the team should be given a list of the planned surgical steps. The task list described below was developed to define each step and provide evidence for each decision that is made along the way.

Initial Operating Room Assessment

The patient is brought into the operating room, and after the induction of general anesthesia all appropriate lines and monitors are placed. Empiric antibiotics should be administered, along with a beta blocker, when indicated. Sequential compression devices should be applied to the lower extremities, with or without pharmacologic prophylaxis. A copy of the endoscopy reports and endoscopic ultrasound, computed tomography, and positron emission tomography images should be available in the room prior to beginning the procedure.
esophagectomy. The single-lumen endotracheal tube or laryngeal mask airway (LMA) is then removed, and a double-lumen endotracheal tube is positioned. A repeat bronchoscopy confirms that the left-sided endotracheal tube is in the left mainstem bronchus, and the tracheal opening on the right side allows for visualization of the carina and the entire right mainstem bronchus. A systems check should include monitoring the pressure in the bronchial cuff to ensure that it is not too high.

Endoscopy

Esophagoscopy should be performed to identify the proximal aspect of the tumor and any abnormal tissue near the tumor, including Barrett’s metaplasia. As long as the tumor is distal to 30 cm from the incisors, an Ivor–Lewis esophagectomy is possible, with an intrathoracic anastomosis. No abnormalities including metaplasia should be visible proximal to the area of planned transaction. Once the endoscopy confirms normal squamous lining proximal to 30 cm from the incisors, the patient can be positioned supine, with the abdomen steriley prepared and draped.

Abdominal Approach

A laparoscopic abdominal approach or open midline incisional approach can be used. The advantage of an initial laparoscopic approach is detection of potentially subclinical metastatic peritoneal or liver disease prior to performing a more invasive incision (Fig. 18.3).

Laparoscopic Approach

In the laparoscopic approach, five laparoscopic abdominal trocars are placed: a 12-mm trocar in the midline or just to the right of midline and two 5-mm trocars on either subcostal area (Fig. 18.4). The right subcostal trocar is used to place a Mediflex liver retractor to retract the liver anteriorly and laterally to the right. An energy source is typically placed through the 12-mm port. A 5- to 10-mm trocar should be placed for the camera in the medial subcostal area, approximately 4 to 5 cm inferior to the subcostal region. After all trocars have been placed safely, abdominal exploration should be performed. Checking for evidence of bowel injury or metastatic disease is necessary before proceeding with the esophagectomy. A minimally invasive approach should only be used if the exact same resection quality can be achieved as in an open approach.

Open Midline Incision

An open abdominal incisional approach can typically be performed through an upper midline laparotomy incision. Alternatively, but less commonly, a chevron or thoracoabdominal incision may be employed. The midline incision extends from the xiphoid down to just above the umbilicus. When open, a self-retaining type of retractor may be used to retract the liver and adjacent costal margin out of the way. A left thoracoabdominal incision is advantageous when the patient has undergone extensive foregut surgery and has excessive scar tissue in the left upper quadrant.

Mobilizing the Esophagus

An energy source is used to divide the pars flaccida or hepatogastric ligament. The left triangular ligament should be divided to allow the left lateral segment of the liver to be retracted. The right crus of the diaphragm should be exposed with an energy device, and the esophagus should be mobilized away from the right crus, stripping the peritoneal lining away to include all tissues. If the patient has a small hiatus, the crus can be divided approximately 1 to 2 cm to enlarge the hiatus for additional dissection. This allows for circumferential dissection around

Esophageal Cancer Staging

**Primary Tumor (T)**

- **Tx**: Primary tumor cannot be assessed
- **T0**: No evidence of primary tumor
- **Tis**: High-grade dysplasia
- **T1**: Tumor invades lamina propria, muscularis mucosae, or submucosa
- **T1a**: Tumor invades lamina propria or muscularis mucosae
- **T1b**: Tumor invades submucosa
- **T2**: Tumor invades muscularis propria
- **T3**: Tumor invades adventitia
- **T4**: Tumor invades adjacent structures
  - **T4a**: Resectable tumor invading pleura, pericardium, or diaphragm
  - **T4b**: Unresectable tumor invading other adjacent structures, such as aorta, vertebral body, trachea, etc.

**Regional Lymph Nodes (N)**

- **Nx**: Regional lymph nodes cannot be assessed
- **N0**: No regional lymph node metastasis
- **N1**: Regional lymph node metastases involving 1 to 2 nodes
- **N2**: Regional lymph node metastases involving 3 to 6 nodes
- **N3**: Regional lymph node metastases involving > 6 nodes

**Distant Metastasis (M)**

- **MX**: Distant metastasis
- **M0**: No distant metastasis (no pathologic M0; use clinical M to complete stage group)
- **M1**: Distant metastasis

**Required for Staging:**

- Location – based on the position of the upper (proximal) edge of the tumor in the esophagus
  - (Upper or middle—cancers above lower border of inferior pulmonary vein; Lower—below inferior pulmonary vein)
- **Grade**

**Clinically Significant:**

- Distance to proximal edge of tumor from incisors
- Distance to distal edge of tumor from incisors
- Number of regional nodes with extracapsular tumor

**Histologic Grade (G)**

- **Grade 0 (HG D)**

**Mobilizing the Stomach**

The right gastroepiploic artery should be identified and preserved as the gastrocolic omentum is divided and the lesser adjacent to the esophagus should be dissected away from the right and left crura. After dissecting in the cranial direction toward the mediastinum, the gastrohepatic ligament should be mobilized toward the lesser curve of the stomach. An appropriately sized hiatus for conduit passage is important as too large a hiatus could result in colon herniation and too tight a hiatus can result in ischemia of the conduit. It is helpful to dissect as far into the chest as is safe before closing the abdomen, as the inferior pulmonary ligament lymph nodes from both sides can be dissected from the abdominal approach. It is usually possible to reach up to the inferior pulmonary vein, depending on patient anatomy.

Section I: General Thoracic Surgery

Fig. 18.5. Development of the posterior esophageal window.

Fig. 18.6. Gastric mobilization with gastroepiploic artery preservation.

Fig. 18.7. Pedicled omental flap.

The posterior esophageal window is entered (see Fig. 18.6, “gastroepiploic artery preservation and omental dissection”). Instead of sparing a small segment of omentum, a larger omental flap can be created to be delivered into the chest to cover the anastomosis (Fig. 18.7). When manipulating the stomach, care should be taken to avoid injury when grasping and the right gastroepiploic artery should be avoided. The division should be completed along the entire greater curve of the stomach up to where the short gastric vessels are encountered. Exposure of the short gastric vessels is enhanced by grasping the posterior aspect of the stomach and rolling the tissue toward the liver and up away from the aorta. The short gastric vessels should be divided with an energy device up to the left crus of the diaphragm. The posterior attachments of the stomach to the pancreas should be divided. The cardia of the stomach should be dissected away from the left crus. The posterior esophageal window should be created, and a Penrose drain placed around the esophagogastric junction. This drain can later be recaptured and pulled into the chest to assist in mobilizing the intrathoracic esophagus. The posterior aspect of the stomach should be dissected away from the pancreas, preserving the right gastric artery. For benign disease, the modification does not typically require a complete esophagectomy or lymphadenectomy.

LEFT GASTRIC ARTERY DIVISION AND CELIAC LYMPH NODE DISSECTION

Once the posterior attachments of the stomach have been divided, the stomach is lifted anteriorly to allow for visualization of the left gastric artery pedicle. The left gastric artery pedicle should be divided either with individual ligation of the artery and vein or with a linear vascular stapler at the level of its origin from the celiac axis taking care to include the lymph node packet.

One should be aware for the presence of any aberrant celiac, gastric, or left hepatic artery anatomy (Fig. 18.8A, 18.8B), especially a replaced left hepatic artery coming completely from the left gastric artery. If this artery is an accessory artery and another left hepatic artery is present, it can typically be divided without consequence. However, if the entire left hepatic artery originates from a left gastric artery, a laparoscopic or open sonographic evaluation of flow dynamics can be used to determine portal flow and compensate when hepatic arterial flow has stopped. If blood flow to the liver is not diminished by more than 50%, the artery can still be divided. If the artery must be preserved, the left gastric artery should be ligated further distally, that is closer to the stomach. This will result in a lesser lymph node acquisition but will prevent hepatic necrosis. A low stapler division of this artery, as proximal as possible, allows for incorporation of all lymphatic tissue to be included with the specimen. Celiac lymph nodes can be dissected at this time and sent as separate pathologic specimens. Left gastric artery lymph nodes are then identified and dissected away from the specimen and identified for permanent specimen pathologic analysis. We recommend sending separately labeled packages to more accurately stage disease.
Chapter 18: Thoracic Approaches to Esophagectomy

CREATING A TUBULARIZED STAPLED GASTRIC CONDUIT

Formation of the gastric conduit begins with dissecting the lesser omentum away from the stomach at the area of the incisura to allow for the placement of the linear stapler (see Fig. 18.9 for stapling and designing the gastric conduit). The stapler should be placed beyond the largest arcade from the right gastric artery, and one linear stapler load should be fired toward the greater curve of the stomach. Multiple firings of the linear stapler progressing toward the greater curvature are required to create the conduit. Starting the stapling at the incisura and proceeding toward the apex of the greater curvature allow for a slightly greater length of gastric conduit to be created.

A 2- to 3-cm-wide conduit is recommended as a narrower conduit is at higher risk of leakage, and a wide conduit may shorten the actual length provided. A retractor should be used from the far left subcostal area to straighten the superior aspect of the stomach, preventing twisting of the stomach or conduit while stapling. Once the staple line has been created, it can be oversewn.

The conduit can be completely separated from the specimen or left partially attached. If the conduit is completely separated, it will need to be sewn back to the specimen at the lesser curve side in two places to prevent rotation as it is delivered into the chest. A stapler can be passed into the lumen of the conduit to create a side-to-side or circular stapled anastomosis. If an omental pedicled flap is created, it should also be tacked to the edge of the conduit to facilitate delivery into the chest.

MOBILIZATION OF THE DUODENUM

The duodenum should be mobilized with a Kocher maneuver to allow the pylorus to reach the level of the esophageal hiatus. The division of the omentum and the posterior antrum attachments should be completed to allow the conduit to be delivered easily into the chest. Any attachments to the pancreas should also be released here, without damaging the right gastric artery that comes off the proper hepatic artery, just distal to the gastro-duodenal artery.

PYLORIC DRAINAGE

Three options are available for addressing the pylorus: pyloroplasty, pyloromyotomy, or paralytic injection (typically 100 to 200 IU botox). Some surgeons do not believe a pyloric drainage procedure is necessary; however, many reports in the literature indicate that delayed gastric emptying can result from inadequate drainage due to a restricting pylorus. It is impossible to identify which patients do not need a drainage procedure; because of this, we advocate performing a drainage procedure in all patients.

Laparoscopic or open pyloroplasty should be performed. The pyloroplasty is performed by placing an initial suture on the superior aspect of the pyloric muscle. Electrocautery using an L-hook allows the creation of a longitudinal incision that extends from the stomach into the duodenum, traversing and dividing the pyloric muscle along the way (Fig. 18.10A, 18.10B). It is also possible to perform a pyloromyotomy instead of a pyloroplasty; if this route is chosen, the pyloric muscle should be divided and the mucosal layer of the stomach and duodenum preserved. A long-handled electrocautery instrument can be used to achieve hemostasis during division of the pyloric muscle, and if a pyloroplasty is used, the incision should be completed all the way through the mucosa, exposing the internal lumen of the internal duodenum and stomach. Internal mucosa exposure is facilitated by using the previously placed stay suture on
Section I: General Thoracic Surgery

Fig. 18.10. Pyloroplasty technique. Longitudinal incision over the pyloric muscle (A) and transverse closure with interrupted sutures (B).

FEEDING TUBE PLACEMENT

As an added safety measure in case of the need for postoperative enteral feeding, a tube jejunostomy should be performed. After the transverse colon has been retracted superiorly, the ligament of Treitz should be identified. Approximately 20 cm distal to this ligament, a segment of jejunum should be identified for jejunostomy tube placement. If the abdomen is open, a standard Witzel-type tube jejunostomy is performed.

Laparoscopic feeding tubes can be placed using a sutured technique, with or without an assist device, or a T-fastener technique. The bowel should be held in place against the anterior abdominal wall, and a subclavian needle should be used to traverse the left anterior abdominal wall, where the bowel meets the anterior abdominal wall, to enter the antimesenteric side of the proximal jejunum. A guide wire should be placed into the lumen of the jejunum and guided distally into the bowel. T-fasteners are placed in all four quadrants around the entry point of the guide wire. A saline injection into the bowel lumen often allows safer and easier passage of intraluminal devices and distends the bowel for easier placement of T-fasteners. As an alternative to T-fasteners, the bowel can be sutured to the anterior abdominal wall as well. The T-fasteners are tightened, and a dilator with an introducer sheath is placed over the guide wire through the left anterior abdominal wall. The dilator and guide wire are simultaneously removed, leaving the introducer sheath and the distal jejunum and allowing placement of the feeding jejunostomy tube through the introducer sheath. A grasper is used to guide the catheter into place. Ensure the back wall of the bowel is not incorporated into the sutures, as this may cause obstruction. The catheter is sewn to the anterior abdominal wall and secured on the outside. In the laparotomy approach, the feeding tube is simply sutured to the anterior abdominal wall directly.

THORACIC INCISIONS

Once the gastric conduit has been created, a thorough inspection should be made to assure hemostasis prior to closing the abdomen. The patient is then taken out of the supine position and positioned in the left lateral decubitus position. All pressure points should be padded. The arms should be placed on an arm board, with an axillary roll placed underneath the axilla. The table should be flexed to maximizing the opening of the intercostal spaces. A thoracoscopic or open approach can be used for the mobilization of the esophagus in the chest.

THORACOSCOPIC INCISIONS

In the thorascoscopic approach, four thorascoscopic trocars are typically placed (see Fig. 18.11 for chest trocar placement). A 3-cm utility port is placed in the posterior axillary line at the seventh intercostal space, just above the diaphragm, and a camera port is placed in the anterior axillary line in the eighth intercostal space. A second access port is placed in the right fifth intercostal space in the anterior axillary line. The fourth trocar maybe placed approximately 2 to 3 cm superior to the port in the posterior axillary line. A port protector may be used at the utility site to retract the soft tissue and facilitate suction, exposure, and instrument passage. One should not use suction in the chest without a vent, as this may cause negative-pressure pulmonary edema of the collapsed lung in addition to compromising visualization.

THORACOTOMY

Open thoracic incisions can be performed using a muscle-sparing or muscle-dividing approach. The advantage of a muscle-sparing approach is the preservation of the chest wall musculature that may be subsequently utilized, should a flap be required for use in the event of a postoperative intrathoracic complication (Fig. 18.12). The incision begins in the inframammary...
removing a long segment of the fifth rib to provide optimal exposure. Epidural analgesia is recommended when an open incision is made, as pain control may be improved compared with a traditional patient-controlled intravenous analgesia.

**LEFT THORACOABDOMINAL APPROACH**

When choosing a left-sided approach for esophagectomy, surgeons must recognize the limitations of this approach. A neck anastomosis will be required if the esophageal resection is to be delivered above 25 to 30 cm. The costal arch will be divided, and if the edges of the margin are not reapproximated carefully, postoperative pain will result from mobility of the unfused ribs. A larger incision, spanning two body cavities, can result in more postoperative pain. The benefit of this approach is the superb exposure provided of the hiatal area, especially in reoperative cases, and the ability to perform a more thorough nodal dissection than that afforded by a transhiatal approach. Another advantage is the single position of the patient during the entire procedure, even when a neck incision is being used to construct the anastomosis.

**THORACIC ESOPHAGEAL DISSECTION AND LYMPHADENECTOMY**

The lung is retracted anteriorly to expose the mediastinum. An energy device is used to incise the pleura on either side of the esophagus, extending from the base of the diaphragm superiorly up to the level of the azygos vein. If an en bloc dissection is the goal, the azygos vein and thoracic duct are taken along with the specimen. The inferior pulmonary ligament is divided and all lymph nodes in this area are identified as an inferior pulmonary ligament lymph node package and sent for permanent histologic evaluation.

A vascular endoscopic stapler or suture ligation is used to divide the azygos vein for additional exposure of the esophagus. This stapler can be passed through a chest tube incision in the anterior axillary line in the seventh intercostal space. Creating this port, even in an open case, provides another passage for retraction instruments and better visualization or camera placement when teaching.

An energy source is used to dissect the esophagus circumferentially starting at the level of the diaphragm though much of this dissection may have been completed from the abdomen. While dissecting toward the abdomen, the esophagus is exposed inferriorly toward the diaphragm and into the abdomen from the chest to reveal the Penrose drain that was left in the abdomen encircling the distal esophagus at the gastroesophageal junction. This Penrose drain should be delivered into the chest and retracted superiorly, allowing identification of the attachments around the esophagus. By pulling up on the Penrose drain, the posterior aspect of the esophagus and all tissue adjacent to the esophagus can be safely divided with an energy device under direct visualization.

When an en bloc lymph node dissection is performed, the azygos vein is removed with the specimen and the thoracic duct is ligated (Fig. 18.13). En bloc esophagectomy includes the following structures: intrathoracic esophagus in continuity with the paraesophageal lymph nodes, thoracic duct, subcarinal (level 7) lymph nodes, low paratracheal lymph nodes, paraaortic lymph nodes, hepatic lymph nodes, celiac lymph nodes, left gastric lymph nodes, splenic artery with associated lymph nodes, spleen, and greater omentum. The resected specimen is bounded anteriorly by the pericardium and membranous trachea, laterally by the right and left pleural cavities, and posteriorly by the aorta and vertebral bodies. Some surgeons advocate routinely ligating the thoracic duct to limit the possibility of a postoperative chylothorax. When performing a modified en bloc dissection, as we prefer to do, the azygos vein, spleen, greater omentum, and thoracic duct are spared, but lymphatic tissue adjacent to the area is included. Lymph nodes should be labeled according to anatomic location to ensure that nodal counts are correct. Figure 18.14 depicts thoracic nodal staging for proper labeling. Dissecting the posterior aspect of the pericardium and the left atrium allows complete dissection around the esophagus, keeping all tissues adjacent to the esophagus with the specimen. The right inferior pulmonary ligament is incised all the way to the level of the right inferior pulmonary vein. The left inferior pulmonary ligament can be identified and lymph nodes dissected from this exposure as well. The esophagus should be mobilized to the level of the azygos vein, avoiding the posterior membranous portion of the trachea and the right and left mainstem bronchi while excising the subcarinal lymph nodes. No energy source is used during dissection of the superior aspect of the esophagus to prevent inadvertent cautery injury to the membranous portion of the trachea or mainstem bronchi.
Esophageal transection should be performed with an energy device or sharp instrument at or above the level of the azygos vein, depending on the tumor location, making sure to achieve a negative margin. It is possible to carry the resection to the apex of the thoracic inlet and create an anastomosis almost to the level as what would be created with a neck anastomosis, but creation of the anastomosis above the level of the azygos vein is more than adequate for distal esophageal lesions (Fig. 18.15). Proximal and distal margins should be clearly marked and frozen sections should be obtained if there is any question about either margin.

**INTRATHORACIC ANASTOMOSIS**

Sutures are placed on the terminal end of the esophagus to hold it without damaging or grasping the tissue that will become the anastomosis. Three types of intrathoracic anastomoses can be created to join the terminal end of the esophagus to the gastric conduit, including the more traditional hand-sewn, stapled side-to-side, and circular stapled. Each is discussed in this chapter in detail. The lack of a serosal layer and the segmental esophageal blood supply puts any anastomosis involving the esophagus at considerable risk underscoring the importance of precise technique and gentle handling of tissue. It is important to limit the dissection to preserve blood supply just proximal to the anastomosis as well as avoiding tension on sutures, which may cut through the wall. We published a propensity-matched analysis of 214 esophagectomies and found the thoracic-stapled anastomosis to be safe, effective, and less likely to cause postoperative stricture or dysphagia than...
the hand-sewn anastomosis, with a similar leak rate (Blackmon et al., 2007).

The conduit should not be delivered into the chest until the surgeon is ready to create the anastomosis. If the tissue is brought into the chest too early, the conduit may be rotated or may obstruct the surgeon’s view. If the conduit is sutured to the specimen, the sutures are simply cut, and the specimen is sent to confirm a negative margin.

If a circular-stapled anastomosis is created, a note should be sent with the specimen noting that the final margin is the end esophageal portion of the doughnut from the stapler. It is important not to deliver too much of the gastric remnant into the chest because redundancy may cause problems later such as dysphagia and poor gastric emptying. Redundant conduit can be resected from the more ischemic tip of the conduit, or the redundant conduit can be tucked back into the abdomen and tacked into position after the anastomosis has been created (Fig. 18.16).

**Circular-Stapled Anastomosis**

A circular-stapled anastomosis can be created by placing a baseball or purse-string suture on the terminal end of the esophagus. Once the suture has run circumferentially around the terminal end of the esophagus passing through muscle and mucosa, the suture is tied tightly around the anvil to close the terminal end of the esophagus. A second purse-string suture is placed slightly higher up from the baseball stitch, circumferentially around the terminal end of the esophagus, leaving a more generous suture on the outside of the esophagus than on the inside; this suture should be tightened as well. If the esophagus does not appear to be tightly fixed around the anvil, an additional suture may be placed to facilitate gathering of the terminal end of the esophagus around the anvil. Any redundant tissue left around the anvil that may creep into the anastomosis will cause a leak. The stapler is placed through the open proximal end of the gastric conduit, and the spike from the EEA stapler is made to exit on a greater curve side of the gastric conduit, approximately 4 to 5 cm away from apex. The anvil is engaged in the stapler that is then fired. This allows the two structures to be joined, creating an end-to-side functional end-to-end anastomosis. Figure 18.17 shows a circular-stapled anastomosis. The gastric conduit staple line should not be any closer than 2 cm to the circular-stapled anastomosis as this will create a watershed area of poor perfusion that may result in a leak.

A significant incidence of stricture formation has been reported when using a size 25 circular-stapled anastomosis; however, some surgeons report no difference for size 25 and 28 staplers. Circular staplers smaller than size 25 should never...
be used. Tips for using the circular stapler are included at the end of this chapter.

**Stapled Side-to-Side Anastomosis**

Once the most proximal end of the gastric conduit has been removed and the gastric conduit is completely stapled with a linear stapler, the conduit can be positioned posterior to the terminal end of the esophagus and sutured into position to lessen tension on the anastomosis. The esophagus should be laid on top of the gastric conduit and again sutured on either side. A gastrotomy is placed on the greater curve side of the gastric conduit, approximately 4 to 5 cm inferior to the most proximal end of the gastric conduit. One fork of the linear stapler is placed in the gastrotomy and the other in the open end of the proximal esophagus and a stapled side-to-side but functional end-to-end anastomosis is created. The anterior rim (the hood) of the esophagus is hand-sewn in an interrupted manner over the opened gastrotomy (Fig. 18.18).

**Hand-Sewn Anastomosis**

To create a hand-sewn anastomosis, the terminal end of the esophagus is placed on top of the gastric conduit, as described in Figure 18.19, for the beginning of a stapled side-to-side anastomosis. A gastrotomy is created on the greater curve side of the stomach to match the esophageal opening. Interrupted sutures are placed circumferentially, connecting the terminal end of the esophagus to the greater curve gastrotomy. A second suture layer is optional, but it may narrow the anastomosis. Interestingly, in a propensity-matched analysis, an intrathoracic hand-sewn anastomosis was associated with higher stricture and dysphagia rates but not higher leakage rates.

**COMPLETING THE THORACIC PORTION**

Once the anastomosis is completed and the gastric conduit tip has been removed, a nasogastric tube should be directed gently into the gastric conduit, with the tip left just above the diaphragm. Warm (cold irrigation may induce fibrillation of the heart) irrigation and insufflation of the conduit should be used to confirm that the anastomosis is completely intact. The conduit should be inspected to ensure that there is no abnormal kinking, redundancy, or malposition. The staple line should be facing the right side of the patient, and the greater curve should be facing toward the left. Figure 18.20 shows the proper orientation of the final conduit and position, with the anastomosis ideally above the level of the azygos vein. The gastric conduit may be tacked into position by suturing it to the mediastinal pleura in several areas. If an omental vascularized pedicled flap has been harvested, the flap can be positioned on top of the anastomosis or between the

**Fig. 18.19.** Hand-sewn thoracic anastomosis. (From Blackmon SH, et al. Propensity-matched analysis of three techniques for intrathoracic esophagogastric anastomosis. Ann Thorac Surg 2007;83(5):1805-1813; discussion 1813.)

**Fig. 18.20.** Proper orientation of a thoracic conduit.
ADDITIONAL TIPS

1. It is important that the patient does not receive any pressors during the operation or in the immediate postoperative period because this may cause conduit ischemia and possible necrosis.

2. The nasogastric tube should be placed into position after the intrathoracic anastomosis has been completed and the terminal end of the gastric conduit has been resected to avoid accidentally including the tube in the staple line.

3. Repeat endoscopy can be performed to evaluate a questionable anastomosis.

4. The nasogastric tube should be secured into position by creating a bridge, placing two ET suction catheters through either nostrils, exiting from the mouth. Umbilical tape can be tied to the terminal end of the two ET suction catheters. Delivery of the ET suction catheters back outside the nostril allows for delivery of either end of the umbilical tape out of the nostril, with the loop passing around the septum. The umbilical tape is loosely tied away from the nostril and tightly tied around the nasogastric tube. This is not meant to hold the nasogastric tube in place but is only a reminder for the patient in the event that they pull on the nasogastric tube. Securing this too tightly may result in nasal septum necrosis.

5. When creating an esophagogastric anastomosis with the circular stapler, it is important to use a stapler with a lower staple height (3.5 mm) and as large a stapler as the esophagus can receive. Larger diameter staplers are better able to staple outside the tissue that is secured to the anvil and are less likely to develop stricture. Using too large a stapler can result in a tear in the esophagus, which can be problematic if the esophagus has been divided in the neck.

6. A laparoscopic anvil grasper will facilitate the creation of a circular-stapled anastomosis and will make it easier to grasp the anvil during manipulation.

**POSTOPERATIVE MANAGEMENT**

In the immediate postoperative period, the patient should be monitored in a specialized setting that is familiar with the care of esophagectomy patients. Many studies have revealed a reduction in postoperative morbidity and mortality rates when the surgery is performed in specialized centers with high resection volumes; the data indicate that survival depends on the volume of esophagectomies done in the institution as much as on the volume performed by the individual surgeon. Postoperative avoidance of intravenous pressors, generous administration of intravenous fluids, aggressive pulmonary toilet (except positive pressure oral ventilation or deep vigorous suctioning), maintaining good conduit decompression with a drainage tube, carefully securing all drainage tubes, early ambulation, and careful management of postoperative atrial fibrillation are just a few of the essential keys to good outcomes in these patients. For a list of common complications after thoracic esophagectomy, refer to Table 18.3. The mortality rate of this procedure is <0% to 4%.

**POSTOPERATIVE INTRATHORACIC LEAK**

The management of postoperative leaks and fistulae is the subject of another chapter, but Martin et al. clearly demonstrated the safety of early reintervention for thoracic leakage with subsequent reduction of postoperative mortality. Early reintervention and the use of muscle flaps have limited the morbidity and mortality rates that were previously associated with intrathoracic leaks. The role of off-label esophageal stenting for leaks and fistulae has yet to be established, but many centers have incorporated this newer and less invasive procedure into practice. The postoperative leakage rate from an intrathoracic anastomosis is higher in patients who have undergone neoadjuvant chemoradiotherapy. The published leak rates in these patients range from 6% to 30%. In patients who have not undergone neoadjuvant treatment, the leakage rate in high-volume centers is typically <10%. The rate is also expected to be higher in patients with a neck anastomosis rather than an intrathoracic anastomosis; this is likely due to relatively more ischemia at the tip of the gastric conduit when brought up into the neck.

**LONG-TERM MORBIDITY**

Patients may develop a stricture after resection, which may require dilatation, revisional surgery, or stenting. Careful consideration of patient complaints will ensure increased satisfaction. Postoperative support groups allow surgeons and patients to learn from each other about postoperative outcomes and management. Dumping syndrome and delayed gastric emptying are well-known complications following esophagectomy. Reflux into the conduit is enhanced when the anastomosis is in a lower position in the chest. Grehlin or other appetite stimulants may lessen the characteristic postoperative weight loss. Postoperative respiratory insufficiency and atelectasis occur more commonly following thoracic esophagectomy, but the incidence of pneumonia is similar, regardless of the approach. Chylothorax, posterior membranous airway tears, and blood loss tend to occur with greater frequency following the transthoracic approach but this varies greatly depending on experience.

**REVISIONAL SURGERY**

Conduits that become redundant or herniate into the chest may require revisional surgery. Incomplete pyloric drainage, paraconduit herniation of abdominal contents, or constricting closure of the diaphragmatic hiatus may also require revision. Luketich et al. described revisional procedures for conduit redundancy, twisting, and incomplete conduit emptying, with excellent results; patients with less than optimal outcomes can benefit from surgical correction of the technical problems that may result from the initial surgical procedure.
The surgeon who wishes to perform esophageal surgery must be facile with multiple approaches since “one size does not fit all.” The emergence of minimally invasive techniques has changed the landscape but not all patients will be candidates for such an approach and every surgeon performing minimally invasive surgery should be intimately familiar with open techniques. There should never be any compromising of oncologic principles simply to carry out an operative procedure that the surgeon prefers. The operative procedure needs to be dictated by patient characteristics and specifically by the tumor. I have previously stated that the ultimate minimally invasive esophageal operation is the transthoracic approach where no thoracic incision is employed, not even small ones used for trocar placement, but this view has clearly been challenged by those who have developed significant expertise with the minimally invasive approaches. No matter the route chosen the bottom line remains the completeness of the resection and the optimal staging of the patient.

There are a number of small technical details that may have a major impact on the surgical procedure. Though an intrathoracic anastomosis is associated with a lower leak rate than a cervical anastomosis, the consequences of an intrathoracic leak can be far greater especially if the leak is inadequately drained or recognition is delayed. Most cervical anastomotic leaks may be managed simply by opening the skin to allow drainage and healing usually occurs without further complication. Stricture formation occurs with high frequency following an anastomotic leak and it probably is best to begin anastomotic dilatation expectantly. I am very concerned about the incidence of stricture following the use of the circular stapler, a device that I do not use. For years I employed a hand-sewn, single-layer anastomosis with excellent results but in recent years I have employed the linear stapler technique popularized by Orringer and described by the authors in this chapter. The opened distal end of the esophageal remnant is placed adjacent to a small gastrostomy made in an appropriate location on the gastric remnant and a single suture is placed in full thickness at the midpoint of what will become the staple line. One blade of the linear stapler is placed in the gastrostomy and the other in the esophageal lumen and the stapler is fired leaving a “hood” of anterior esophagus that is sewn closed. This creates a very large anastomosis that has been associated with a lower leak rate than previously seen with other techniques. When working in the neck, care should be taken to avoid placing a retractor on the tracheoesophageal groove so as to not injure the recurrent laryngeal nerve.

When an intrathoracic anastomosis is used, a contrast swallow should be obtained on the fifth or sixth postoperative day to assure the absence of a leak. I do not routinely obtain a swallow with a cervical anastomosis but simply give the patient some grape juice and observe to see if any purple color is seen in the drain collection bulb. Clear liquids are started as soon as it is determined that no leak is present. Occasionally, a leak will present within a day or two of a seemingly negative study. Gastric conduit necrosis fortunately is rarely seen but may be a devastating complication. When this occurs, the signs are usually present within the first 2 days following resection. The surgeon must be vigilant and maintain a high index of suspicion if the patient is febrile or hypotension occurs or if the patient simply does not “look right.” There should be no hesitation to perform an endoscopy to visualize the gastric remnant if there is any concern regarding the viability of the conduit. If there is evidence of necrosis, the conduit

(continued)
must be taken down and resected with the patient being left with a cervical esophagostomy and facing the prospect of subsequent reconstitution of the gastrointestinal tract with a colon interposition, should they make it through the postoperative period.

There is ample evidence in the literature that supports the concept that esophagectomy should be done preferentially in high volume centers where the morbidity and mortality associated with the operation are significantly lower than that seen in centers that do few esophagectomies. This is especially true if the patient has undergone a course of neoadjuvant treatment with chemotherapy and radiation therapy. These are complex procedures where the technical performance of the operation as well as the postoperative care must be optimal.
INTRODUCTION

Minimally invasive surgical approaches are being increasingly implemented in the management of esophageal disease. The continued challenge for the minimally invasive surgeon is to maintain the fundamental principles of esophageal surgery that have been established with decades of open experience, while avoiding ill-advised shortcuts. The more complex the esophageal intervention, the more likely we are to see difficulty in reproducing the key technical steps of any given minimally invasive procedure. In most cases it is not the intent of the surgeon to perform a less than perfect operation, but one may be prodded by reports from other centers, as well as by patients and referring physicians seeking good results from small incisions. Therefore, as we evolve toward a less invasive culture and embrace new technologies, it is important that we continue to critically interpret and publish our results, while adopting a thoughtful attitude toward accomplishing the best outcomes possible.

This chapter summarizes the role of minimally invasive surgery in the treatment of esophageal cancer. Though laparoscopic fundoplication represents one of the cornerstones of minimally invasive esophageal surgery, this topic is discussed in detail in the chapter on antireflux procedures (Chapter 16). Similarly, other advanced minimally invasive esophageal techniques including esophageal staging techniques (Chapter 2), myotomy with fundoplication for esophageal motility disorders (Chapter 20), diverticulectomy (Chapter 22), palliative esophageal procedures (Chapter 21), and paraesophageal hernia repair with or without gastroplasty (Chapter 35) are covered in this text. The minimally invasive approach to esophagectomy highlighted in this chapter includes a detailed description of operative technique as well as a discussion of the published outcomes with comparison to the comparable open procedures. Complex procedures such as minimally invasive esophagectomy (MIE) are routinely being performed in only a limited number of specialized centers. Prospective studies ultimately will be required to objectively identify the benefits and limitations of these minimally invasive approaches.

BACKGROUND—ESOPHAGEAL CANCER

Esophageal cancer is the sixth leading cause of cancer-related death worldwide. In the United States, there will be an estimated 17,460 new cases of esophageal cancer diagnosed in 2012, with over 15,070 deaths (ninth leading cause of cancer-related deaths in the United States). The incidence of esophageal cancer increases steadily with age, with the median age of diagnosis being 68 years. Though squamous cell carcinoma has been demonstrated to be four to five times more common in African Americans, the incidence of adenocarcinoma has been increasing rapidly among Caucasians. In the mid-1990s, adenocarcinoma overtook squamous cell carcinoma as the most common type of esophageal cancer in the United States. Risk factors for the development of adenocarcinoma include chronic gastroesophageal reflux disease (GERD), obesity, and the presence of Barrett’s esophagus. Esophageal adenocarcinoma is currently the solid malignancy with the most rapidly increasing incidence in the United States and the Western world, having increased by almost 600% since the 1970s. Overall survival rates, however, remain grim, ranging between 5% and 16%. The introduction of new molecular diagnostic tests in addition to new and emerging therapeutic techniques, and the development of more effective multimodality management strategies, provide hope for earlier identification and hopefully improved outcomes in the management of this lethal condition.

ENDOSCOPIC MANAGEMENT OF HIGH-GR ADE DYSPLASIA AND SUPERFICIAL ESOPHAGEAL CANCER

High-grade dysplasia (HGD), referred to by some as carcinoma in situ, is characterized by malignant histologic findings that are confined to the esophageal epithelium and do not penetrate the basement membrane. HGD is believed to represent a late step in the dysplasia–carcinoma sequence, and can exist both as an isolated lesion and in association with invasive cancer. Although not all patients with HGD have, or will develop, cancer, malignant progression has been documented in 16% to 59% of patients followed for more than 5 years. Detection is notoriously difficult due to the lack of visible mucosal changes, and diagnosis is complicated by significant interobserver variability in the interpretation of the pathologic specimens. Esophagoscopy employing the Seattle protocol (four-quadrant jumbo biopsies taken every 1 cm) remains the standard method for evaluating segments of Barrett’s esophagus. When HGD is suspected based upon pathologic evaluation, confirmation of the diagnosis by an independent pathologist is performed.

The principal management options for patients diagnosed with HGD include endoscopic surveillance, mucosal ablation, or esophagectomy. Intensive endoscopic surveillance can be performed every 3 to 6 months in the setting of HGD, with surgical or ablative therapy being employed once there is definitive evidence of adenocarcinoma. Although it is true that not all patients with HGD will go on to develop cancer, by the time biopsy specimens reveal HGD, between 40% and 60% patients will already have an invasive malignancy. Intensive surveillance strategies might avoid the risks associated with esophageal resection, but there has not been a clear demonstration that current intensive surveillance protocols are cost-effective or improve...
mortality from esophageal cancer. Extensive work is underway evaluating methods to enhance the yield of surveillance protocols utilizing improved imaging modalities (e.g., fluorescence endoscopy, narrow-band imaging). However, at this time, none of these modalities has been clearly established as the standard of care in the management of HGD and early esophageal cancer.

Endoscopic ablation represents another option in the treatment of HGD or carcinoma in situ. The intent of this procedure is to eradicate the abnormal Barrett’s epithelium to allow for subsequent restoration of normal squamous mucosa. Multiple techniques have been developed to selectively eradicate Barrett’s mucosa and intramucosal carcinomas, including photodynamic therapy, endoscopic mucosal resection (EMR), and radiofrequency ablation (RFA).

Photodynamic Therapy—Technique

Photodynamic therapy (PDT) employs a photosensitizing drug (porfimer sodium) that is absorbed and retained at higher concentrations in neoplastic tissue when compared with normal tissue. Porfimer sodium (Axcan Scandipharm, Inc., Birmingham, AL) is injected at a dose of 2 mg/kg, and is allowed to circulate for 24 to 48 hours prior to treatment. Endoscopy is performed, and a PDT probe of appropriate length (1 cm, 2.5 cm, or 5 cm) is chosen and deployed through the endoscope under direct visual guidance. The probe is typically deployed in the stomach, pulled back to the designated site of treatment, and maintained in immediate proximity to the targeted lesion throughout the course of therapy. Focal stimulation of porfimer sodium in vivo with a laser light of appropriate wavelength (630 nm) induces a photochemical reaction that results in mucosal destruction. Total light dose ranges between 175 and 300 J/cm. After the initial application is completed, a second look is performed typically within 48 hours to permit assessment of treatment response, perform endoscopic mucosal debridement, and to apply a second dose of PDT, if needed. Patients are maintained on a liquid diet between PDT treatments advancing to a soft diet in 2 to 3 days following the completion of therapy.

Photodynamic Therapy—Results

The endoscopic ablation of Barrett’s esophagus and superficial cancers with PDT has been evaluated in several prospective studies. Complete ablation of HGD or carcinoma in situ can be accomplished in 50% to 77% of cases, with complete squamous reepithelialization occurring in about half. Residual submucosal intestinal metaplasia has been identified in 5% to 50% of patients after PDT, raising concerns regarding the possibility of continued malignant progression. The most common complication following PDT is stricture formation, occurring in one-third to half of the patients. Other complications following PDT include cutaneous photosensitivity, chest pain, nausea, pleural effusions, Candida esophagitis, atrial fibrillation, and odynophagia. Although more severe complications such as esophageal perforation and tracheoesophageal fistula formation have been reported, they are exceedingly rare (less than 1% in most large studies). Progression to cancer following PDT for HGD has been reported in 5% to 13% of patients. Our experience at the University of Pittsburgh included 50 high-risk patients with either HGD or localized esophageal cancer. At a mean follow-up of 28.1 months, the intent-to-treat success rate was 38% in HGD and 30% in cases of focal carcinoma. Strictures occurred in 42% of patients.

Endoscopic Mucosal Resection—Technique

EMR is also a viable treatment option in patients with nodular or focal HGD or early esophageal cancer. This group of patients has a lower risk of lymph node metastasis, and thus local resection techniques can be performed with the intent to cure. Advantages of EMR also include the generation of a tissue specimen that provides information on stage and margins and lower morbidity and mortality when compared with esophageal resection.

At endoscopy, the targeted lesion must be carefully assessed to determine the extent of resection. Visual delineation of the borders of the lesion can be enhanced by the use of chromoendoscopy or narrow-band imaging. Endoscopic ultrasound (EUS) is also frequently utilized to assess lesion depth and the status of the periesophageal lymph nodes. The EMR technique involves raising the mucosal or submucosal target area by intramural saline and/or suction and then performing a snare resection (Fig. 19.1). This technique can be performed focally or circumferentially. The most common EMR technique utilized in the esophagus is the “cup and suction” or EMR-cap technique. Following injection of saline (with or without epinephrine or methylene blue) into the submucosa to elevate the targeted lesion, a plastic cap is then positioned over the targeted site and the mucosa is drawn into the cap by suction. A snare that is positioned around the cap is then closed around the base of the lesion, which is then removed by electrocautery (Fig. 19.2).

Another commonly employed EMR technique is band ligation. The targeted lesion is suctioned into a ligation cylinder (Duette System, Cook Medical, Winston-Salem, NC) and a band is deployed at the base, which results in the formation of a pseudopolyp. A snare is deployed just below the base of the pseudopolyp to excise the lesion. Other EMR techniques include the strip biopsy, which is most useful for raised or polypoid lesions. No submucosal injection is performed with this technique.

Fig. 19.1. Endoscopic mucosal resection. (A) Localized polypoid lesion involving the distal esophagus. (B) Appearance of mucosa following endoscopic mucosal resection. (Reprinted from Peters FP, et al. Endoscopic treatment of high-grade dysplasia and early stage cancer in Barrett’s esophagus. Gastrointest Endosc 2005;61:506-514, Copyright (2005) with permission from Elsevier.)
A snare is introduced through the working channel and the targeted lesion is removed by electrocautery. A variation of the strip biopsy is the “inject, lift, and cut” technique, which requires a two-channel endoscope. Following submucosal injection, the lesion is lifted by forceps introduced through one channel, and removed by snare electrocautery performed via the second channel.

After resection, the specimen is oriented and submitted to pathology for assessment of pathologic T stage, surgical margins, and for the presence of lymphovascular invasion. For lesions with negative margins and no lymphovascular invasion the probability of a curative resection is >95%. For lesions where margin status remains in question, close endoscopic follow-up is warranted to rule out the possibility of local recurrence. If there is suspicion of lymphovascular invasion or nodal involvement, standard surgical resection with nodal dissection is recommended.

Endoscopic Mucosal Resection—Results

In properly selected patients, EMR can achieve complete remission in over 95% of cases, with corresponding estimated 5-year survival rates as high as 98%. When local recurrences are encountered, they can almost always be treated with repeat EMR. EMR is now being performed with high success, both focally and circumferentially, for HGD and superficial cancers. Bleeding is the most common minor complication. Esophageal stricture is a late complication and is reported in up to 30% of cases, especially when EMR is performed circumferentially or when combined with other ablative modalities such as PDT. Risk of esophageal perforation is less than 1%.

In conclusion, EMR is a viable technique for the management of HGD and early esophageal cancer. It can be labor intensive and time consuming, especially for larger lesions. Large lesions typically require piecemeal excision, which can complicate assessment of surgical margins. Further randomized studies with long-term follow-up will be required to fully delineate the potential benefits of this approach.

Endoscopic Submucosal Dissection—Technique

Endoscopic submucosal dissection (ESD) represents an extension of the EMR technique and employs an electrocautery knife to dissect and excise larger (>2 cm) mucosal lesions in an en bloc fashion. Similar to EMR, the borders of the lesion are delineated by scoring the mucosa with electrocautery. A saline–epinephrine solution is then injected in the submucosal plane. Other injectable solutions (e.g., hyaluronic acid) can be utilized to maintain the lifting effect on the mucosa, which is then excised utilizing an endoscopic electrocautery knife. A peripheral incision is performed to initiate the dissection. Submucosal fibers are sequentially hooked and cut, and hemostasis is maintained by the use of electrocautery (Fig. 19.3). A transparent cap can be utilized on the tip of the endoscope to enhance exposure. A variety of endoscopic cutting knives has been utilized as reported in the literature, including the Needle Knife (Olympus, Tokyo, Japan), Hook Knife (Olympus, Tokyo, Japan), Flex Knife (Olympus, Tokyo, Japan), Triangle Tip Knife (Olympus, Tokyo, Japan), IT Knife 2 (Olympus, Tokyo, Japan), Duoknife (Olympus, Tokyo, Japan), Safe Knife (Pentax Corp., Omiya, Japan), Flush Knife (Fujinon Corp, Omiya, Japan), and Hybrid Knife (Erbe Corp, Tübingen, Germany).

Endoscopic Submucosal Dissection—Results

Similar to EMR, successful en bloc resection achieving negative margins has been reported in 95% to 100% of cases with the ESD technique, with recurrence reported in <3% of cases in small series. Complications of ESD include bleeding, perforation, stricture, and pain. Bleeding is the most common complication (7% to 11%), and can be managed with electrocautery and applications of topical epinephrine. Specialized endograspers (Cograsper, Olympus, Tokyo, Japan) are particularly useful in applying electrocautery to areas of bleeding during ESD. Perforation rates, as reported, range from 0% to 1%. Stricture is most common in cases that involve resection of greater than one-half of the esophageal circumference, and is managed with periodic esophageal dilation.

A recent report from a multinational collaborative in Europe (N = 27 esophageal cases) demonstrated successful en bloc resection in only 77.1% of cases. Morbidity rates were 18.5%, including three cases of perforation (11.1%) and a postprocedural bleeding rate of 7.4%. These data indicate that significant additional experience must be gained with this technique to confirm the promising initial experience reported from Japan. Furthermore, long-term results and survival data are lacking for the ESD technique and this approach will need to be validated by prospective, randomized trials prior to more widely applied clinical application.
Radiofrequency Ablation—
Technique

The RFA system (Halo™ System, BARRX Medical Corporation, Inc., Sunnyvale, CA) is a balloon-based catheter ablation system that applies radiofrequency energy via a 3 cm bipolar microelectrode with 60 electrode rings. Radiofrequency energy is delivered through the balloon, generating heat which leads to coagulative necrosis and tissue destruction in the adjacent tissue. A sizing balloon is initially deployed to measure the inner diameter of the targeted segment. The appropriately sized balloon delivery system is then advanced into position over a wire and RFA is performed per a standardized protocol. The closely spaced circumferential electrodes deliver the radiofrequency energy pulse in less than 1 second, accomplishing a uniform distribution of energy density. The depth of ablation is typically limited to the muscularis mucosa. This is slightly more superficial than the EMR and ESD techniques, which excise tissue down to the level of the submucosa. As a result, RFA has been thought to produce a lower rate of stricture formation. The catheter can be repositioned to treat the entire length of Barrett’s esophagus as required (Fig. 19.4). Noncircumferential probes (Halo™ System, BARRX Medical Corporation, Inc., Sunnyvale, CA) that can apply energy to focal islands of residual Barrett’s tissue are available.

Radiofrequency Ablation—Results

In a study of 70 patients with Barrett’s esophagus with no dysplasia treated with RFA (12-month follow-up), metaplasia was completely eradicated in 70% of patients, and partially eliminated in 25% of patients. Adverse events were rare and included chest discomfort and fever. No strictures or residual subsquamous metaplasia were noted. In a multicenter U.S. registry report on 142 patients with HGD treated with RFA, complete resolution was accomplished in 90.2% of patients with HGD, 80.4% with dysplasia, and 54.3% of patients with intestinal metaplasia.

In a multicenter, sham-controlled study evaluating the use of RFA (N = 84) for Barrett’s esophagus with dysplasia, RFA produced complete eradication of dysplastic Barrett’s esophagus in 77.4% of patients, as compared to 2.3% among controls (P < 0.001). Patients in the RFA group had a reduced rate of dysplastic progression (3.6% vs. 16.3%; P = 0.03) during follow-up and a lower incidence of cancer (1.2% vs. 9.3%; P = 0.045). Bleeding occurred in one patient and the esophageal stricture rate was 6.0%. On long-term follow-up (mean follow-up = 3 years), RFA was associated with eradication of dysplasia in >85% of patients, with no evidence of intestinal metaplasia.
in >75%. The rate of neoplastic progression was 1 in 73 patient-years, and the rate of progression to carcinoma was 1 in 181 patient-years.

There is increasing interest in the combination of modalities in the management of Barrett’s esophagus with HGD and/or early cancer. The combination of EMR with RFA has been evaluated in a European multicenter study, in which 24 patients with HGD or carcinoma in situ were treated by EMR for visible mucosal abnormalities, followed by serial RFA to treat the underlying Barrett’s esophagus. At a median follow-up of 22 months, neoplasia and intestinal metaplasia were eradicated in 95% and 88% of patients, respectively. The combination of RFA followed by antireflux surgery has also been evaluated in a series of 14 patients, and was shown to be performed safely with no significant difficulties in subsequent esophageal dissection. In this study, complete eradication of Barrett’s metaplasia was accomplished in 50% of patients. No progression of Barrett’s esophagus was observed.

These data suggest that RFA is a safe and durable procedure for the management of patients with Barrett’s esophagus with dysplasia. RFA can be performed with low morbidity and can be combined safely with other modalities as required to augment the treatment response.

**Endoscopic Ablation—Alternative Techniques**

A variety of other ablative approaches has been utilized in the management of Barrett’s esophagus with HGD or superficial cancer. Nd:YAG laser ablation, argon plasma coagulation (APC), multipolar electrocoagulation (MPEC), and cryotherapy are all capable of ablating neoplastic and metaplastic mucosa, followed by repopulation with normal squamous epithelium. YAG laser, APC, and MPEC can eradicate Barrett’s mucosa with success rates ranging from 25% to 88% in reported series, but can be associated with a higher risk of perforation and stricture formation. Cryotherapy is a simple technique that can ablate Barrett’s mucosa via a low-pressure liquid nitrogen spray. This technique has been shown to downstage HGD or eliminate cancer in 80% of patients with intramucosal carcinoma, and 68% with HGD at 1-year follow-up. Further experience with these alternative modalities is required, which are currently best viewed as adjuncts in the multimodality approach to patients with HGD and superficial esophageal cancer.

**Endoscopic Therapy—Conclusions**

In a position statement by the American Gastroenterological Association, eradication of Barrett’s esophagus with HGD by RFA, EMR, or PDT is recommended in lieu of intensive endoscopic surveillance. EMR (or ESD) is specifically recommended in cases where there is a visible mucosal irregularity in an effort to most accurately determine the T stage of the neoplastic lesion. Given the frequent multifocality of Barrett’s dysplasia following EMR, a concomitant ablative procedure (e.g., RFA) is recommended as required to ensure complete eradication of disease.

**MINIMALLY INVASIVE ESOPHAGECTOMY**

MIE is a complex and technically challenging procedure that has evolved over the past two decades. Various techniques have been developed over time, including hybrid approaches that combine open surgery with either thoracoscopic or laparoscopic, as well as totally MIE techniques (transhiatal, three-hole, Ivor–Lewis).

Variants of MIE include “thoracoscopic esophagectomy”, which utilizes thoracoscopy to achieve esophageal mobilization in combination with standard laparotomy and a cervical incision for the completion of the esophagectomy. Other approaches include “lap-assisted esophagectomy”, where laparoscopy is utilized for mobilization and preparation of the gastric tube, and “hand-assisted laparoscopic transhiatal esophagectomy”, which introduces a hand port to assist with mediastinal mobilization during transhiatal esophagectomy (THE). Also, robotic thoracoscopic/laparotomy approaches have been developed utilizing the da Vinci operating robot.

Totally MIE (total MIE) techniques have been developed utilizing thoracoscopic and/or laparoscopic exclusively. The most popular totally minimally invasive approaches to esophagectomy are the Ivor–Lewis MIE and the three-hole (McKeown) MIE. In some centers, a complete thoracoscopic/laparoscopic approach is not feasible or preferred, and the use of hand-assisted techniques in the approach to esophagectomy has been explored. While offering some potential advantage in cases where organ integrity is important, a hand inserted near the esophageal hiatus or into the mediastinum frequently obscures the view and is generally unnecessary during MIE. The optimal minimally invasive approach remains to be determined but surgeon experience and preference must be considered as major factors. Until further randomized data become available, the chosen approach should be based on tumor and patient characteristics, as well as the surgeon’s personal preference and expertise.

The first totally laparoscopic esophagectomy at the University of Pittsburgh was performed in 1996. This initial approach has evolved into one combining thoracoscopic and laparoscopy for several reasons. Esophageal mobilization can be tedious and cumbersome via a completely laparoscopic approach. In addition, visualization of paraesophageal structures (such as the inferior pulmonary vein and the main stem bronchi) and the performance of mediastinal lymph node dissection can be very limited when employing an exclusively transabdominal approach. In the first 77 patients at the University of Pittsburgh undergoing MIE, a combined thoracoscopic/laparoscopic approach was utilized in the majority, achieving a median length of hospital stay of 7 days, and a stage-specific survival similar to or better than open-surgery results. The authors have now performed MIE on over 1,000 patients with HGD or cancer. Over time, our approach to MIE has evolved from a three-hole (McKeown) technique to a minimally invasive Ivor–Lewis esophagectomy. The Ivor–Lewis approach avoids the morbidity of a neck anastomosis (higher anastomotic leak and stricture rates, recurrent laryngeal nerve injury, and dysphagia). We currently reserve three-hole MIE for patients with long-segment Barrett’s esophagus and proximal tumors, where there is concern about achieving adequate proximal resection margins. Reduced postoperative pain and shorter hospital stay are noted when comparing MIE with open approaches. Furthermore, MIE may be associated with reduced overall postoperative morbidity, while achieving comparable oncologic outcomes and long-term survival.

MIE should be performed by surgeons who have extensive experience in minimally invasive esophageal surgery. Patients must be deemed fit for operation, and must have resectable lesions as characterized by EUS or computed tomography (CT). During the early portion of the learning curve, surgeons should consider performing MIE in patients who have HGD, small tumors, a favorable body habitus, and minimal or no prior abdominal or thoracic surgery. As experience increases, we have found that previous abdominal or thoracic surgery and preoperative chemotherapy or radiation therapy do not represent contraindications to a minimally invasive approach for either staging or resection of esophageal cancer.
Minimally Invasive Ivor–Lewis Esophagectomy—Technique

The procedure is begun with an on-table esophagogastroduodenoscopy (EGD) to assess tumor location and the suitability of the gastric conduit for reconstruction. If the EGD, EUS, or CT scan findings suggest gastric extension, T4 local invasion, or possible metastases, we perform a staging laparoscopy, staging thoracoscopy, or both. The patient is then intubated with a double-lumen endotracheal tube to permit single-lung ventilation, and the laparoscopic portion is performed first. Five laparoscopic ports are inserted as demonstrated in Figure 19.5, starting with a 10-mm port placed via direct cut-down two-thirds down a line joining the xiphoid process and umbilicus and 3 cm to the right of the midline. The abdomen is insufflated with carbon dioxide to a pressure of 15 mmHg and the remaining ports are placed. We routinely use a 30 degree 10 mm laparoscope for visualization.

Staging laparoscopy is then performed, and if no metastatic disease is present we continue with gastric mobilization by dividing the gastrohepatic ligament. The right and left crus are dissected taking care to avoid early division of the phrenoesophageal ligament to prevent loss of pneumoperitoneum. The short gastric arteries and gastrocolic omentum are then divided with ultrasonic coagulating shears, while preserving the right gastroepiploic arcade. In some cases, we mobilize an omental pedicle at the mid- to upper-third of the greater gastric curve. This pedicle is supplied by two feeding vessels and is used later in the procedure to wrap the anastomosis. The stomach is then rotated to the patient’s right and all posterior attachments to the pancreas are divided. A celiac lymph node dissection is performed along the splenic artery toward the splenic hilum. The left gastric artery and vein are then exposed and divided with an endoscopic linear cutting stapler, taking care to divide the vessels proximally to allow resection of the lesser curve lymph nodes and fat with the specimen. The pylorus and antrum are then mobilized to allow the pylorus to reach the right crus without undue tension. The right gastric vessels are preserved. Using ultrasonic shears and 2-0 braided nonabsorbable suture, a Heineke-Mikulicz pyloroplasty is performed (Fig. 19.6). A gastric conduit is then created with multiple firings of the endoscopic linear cutting stapler using 3.5 to 4.8 mm staples, starting along the lesser curve at the level of the antrum and directing the stapler toward the angle of His (Fig. 19.7). For exposure of the stomach during this part of the procedure, the assistant grasps the

Fig. 19.6. Laparoscopic pyloroplasty. (A) The pylorus is divided longitudinally after placement of stay sutures. (B) The pylorus is then closed transversely with interrupted 2-0 Surgidac sutures. A portion of the omentum may be tacked over the closure to provide additional coverage.
gastric fundus and applies traction toward the spleen. At the same time, the antrum is retracted inferiorly and to the patient’s right to maximize conduit length. We limit conduit diameter to 4 to 5 cm to optimize emptying. The conduit is then sutured to the specimen with two 2-0 Endo Stitches (U.S. Surgical, Norwalk, CT) (Fig. 19.8). Alignment of the conduit is maintained to prevent rotation, with the staple line facing the patient’s right at all times. If harvested, the omental pedicle is tacked to the proximal conduit to prevent traction injury during advancement into the chest.

A feeding jejunostomy tube is then placed. With the patient flat, the transverse colon is retracted cephalad and the ligament of Treitz is identified. A 10-mm right lower quadrant port is inserted and the jejunum is grasped 30 cm distal to the ligament of Treitz and elevated toward the patient’s left abdominal wall. The jejunum is tacked to the anterior abdominal wall with a single Endo Stitch and a needle jejunostomy catheter is inserted just distal to the tacking stitch under laparoscopic visualization. Intraluminal placement is confirmed by bowel distention after injecting 10 ml of air through the catheter. Three circumferential 2-0 Endo Stitches are placed at the catheter entry site to secure that part of the jejunum to the anterior abdominal wall. The jejunum distal to the catheter insertion site is then secured to the anterior abdominal wall along a distance of several centimeters with interrupted 2-0 Endo Stitches to prevent torsion of that segment of bowel. Once this is accomplished, the phrenoesophageal ligament is divided circumferentially to allow mobilization of the distal esophagus and passage of the conduit into the chest. A Penrose drain can be placed around the distal esophagus to aid with retraction. An omental patch is then used to cover the pyloroplasty and the posterior crura are approximated with 0 Endo Stitches to prevent hiatal herniation.

The patient is then repositioned in a left lateral decubitus position for the thoracoscopic portion of the procedure. Five ports are then inserted in the right chest as follows (Fig. 19.9): a 10-mm port is placed in the seventh intercostal space, midaxillary line for the thoracoscope; a second 10 mm port is placed in the eighth intercostal space 2 cm posterior to the posterior axillary line for the ultrasonic shears; a final 10 mm port is placed in the anterior axillary line at the level of the fourth intercostal space, and is used for placement of a fan retractor to assist with anteromedial lung retraction and exposure of the esophageal bed; a 5-mm port is placed posterior to the tip of the scapula. An additional 5 mm port can be placed anteriorly in the fifth or sixth intercostal space for suction. A retracting suture (0-Surgidac; U.S. Surgical Corp., Norwalk, CT), is placed in the central tendon of the diaphragm to improve visualization of the hiatus and is brought out of the inferior anterior chest wall through a 1-mm skin incision using the Endo Close device (U.S. Surgical Corp., Norwalk, CT). This traction suture allows downward retraction on the diaphragm without the need for manual retraction, and provides excellent exposure of the distal esophagus at the level of the diaphragm.
Next, the inferior pulmonary ligament is divided. The mediastinal pleura overlying the esophagus is divided anteriorly and posteriorly, and the entire thoracic esophagus is exposed. The authors generally choose a plane distant to the tumor while dissecting circumferentially around the esophagus. Encircling the esophagus with a Penrose drain facilitates traction and exposure (Fig. 19.10). Circumferential mobilization of the esophagus is then performed to include the surrounding lymph nodes, periesophageal tissue, and fat from the level of the diaphragm to the thoracic inlet. The dissection is carried along the pericardium and aorta and the contralateral mediastinal pleura, up to (but not including) the thoracic duct and azygous vein laterally. Aortoesophageal vessels are sequentially ligated and divided with the Autosonic shears (U.S. Surgical Corp., Norwalk, CT). Clips are deployed liberally during this portion of the dissection (especially laterally in the vicinity of the thoracic duct) to minimize the risks of bleeding and thoracic duct leak. The azygous vein is isolated circumferentially and divided using the Endo GIA stapler with a vascular load (U.S. Surgical Corp., Norwalk, CT). Dissection is then carried proximally toward the thoracic inlet along a plane immediately adjacent to the esophagus to minimize the risk of injury to the recurrent laryngeal nerve and posterior trachea. Care is taken to preserve the pleura above the azygous vein. We believe that this pleural layer helps to maintain the gastric tube in a mediastinal location, and may also help to seal the plane around the gastric tube near the thoracic inlet, thereby minimizing the extension of a cervical leak downward into the chest. The authors do not routinely dissect out the recurrent laryngeal lymph nodes or perform a cervical lymph node dissection. The distalesophagus and conduit are then pulled gently into the chest taking care to maintain proper conduit orientation (Fig. 19.11). The proximal esophagus is then divided at or above the level of the azygous vein utilizing scissors. The sutures securing the proximal stomach to the conduit are then cut. The eighth intercostal space incision is enlarged to a length of approximately 5 cm without rib spreading, and a wound protector (Applied Medical, Rancho Santa Margarita, CA) is placed to facilitate removal of the esophagus. The specimen is sent for frozen section analysis to assess the esophageal and gastric margins. The anvil of the 28-mm end-to-end anastomosis (EEA) stapler is inserted into the esophagus and secured with two 2-0 purse string Endo Stitch sutures. The EEA stapler is then introduced into the chest through the eighth interspace incision. A gastrotomy is created near the tip of the conduit to allow insertion of the EEA staple. The stomach is gently pulled over the tip of the EEA staple, and is advanced cephalad to meet the anvil within the proximal esophagus (Fig. 19.12). An end-to-side anastomosis is thus created between the esophagus and conduit above the level of the azygous vein. The remaining gastrotomy defect is closed with the Endo GIA stapler (Fig. 19.13). If harvested, the omental pedicle is wrapped circumferentially around the anastomosis and secured with 2-0 Endo Stitches. The intercostal nerves are then blocked with 1 to 2 cc of 0.5% bupivacaine in dilute epinephrine for

control of immediate postoperative pain. A nasogastric tube is inserted under direct vision with the tip positioned at the level of the hiatus, and a 28F chest tube is inserted through the camera port and directed posteriorly. The conduit is then tacked to the hiatus with several 2-0 Endo Stitches to prevent herniation. A #10 Jackson-Pratt drain is placed directly posterior to the anastomosis and brought out of the skin through a stab incision at the costophrenic angle. The lung is reinflated and the port sites are closed.

Minimally Invasive Three-Hole Esophagectomy—Technique

Previously, our preference was a three-hole (McKeown) MIE. The thorascopic and laparoscopic portions of the procedure are essentially identical to those described above with the difference that the thorascopscopic part is performed first. The proximal esophageal dissection is carried proximally through the thoracic inlet to the base of the neck. The patient is then positioned supine and the laparoscopic portion is completed. Division of the phrenoesophageal membrane is performed last to prevent escape of pneumoperitoneum into the chest. A 4 to 6 cm horizontal left neck incision is then made two fingerbreadths above the sternal notch. The cervical esophagus is mobilized and exposed. A finger or sponge stick is used to retract the thyroid and avoid injury to the recurrent laryngeal nerve. The dissection is carried distally, until the thoracic dissection plane is encountered. The esophagus is divided 1 to 2 cm below the cricopharyngeus, and the esophagogastric specimen is carefully pulled out of the wound while the laparoscopic assistant carefully delivers the specimen and gastric tube in proper alignment into the mediastinum (Fig. 19.14). The specimen is sent to pathology for frozen section analysis of the surgical margins. An anastomosis is performed between the esophagus and gastric tube using a hand-sewn, end–side EEA or side–side technique with an Endo GIA II stapler. When a McKeown MIE is performed, we prefer a very high anastomosis to ensure adequate resection of any tumor or Barrett’s involvement, as well as to enable anastomotic leak drainage through the neck incision. A nasogastric tube is passed through the anastomosis and distally into the gastric tube for postoperative decompression.

Fig. 19.12. Intrathoracic EEA anastomosis.
Any redundant gastric conduit is then pulled back into the abdomen under direct visualization. The gastric tube is tacked to the diaphragm to prevent herniation of abdominal contents into the chest, using the Endo Stitch. The abdominal instrumentation is withdrawn and the ports are closed. The skin of the neck is loosely approximated with staples. The completed reconstruction is shown in Figure 19.15.

**Minimally Invasive Esophagectomy—Results**

We reported our initial experience with 222 cases of MIE at the University of Pittsburgh in 2003. The median age was 66.5 years (range 39 to 89). The gender distribution was 186 (84%) men and 36 (26%) women. Preoperative indications for surgery included carcinoma (79%) and HGD (21%). Neoadjuvant chemotherapy was used in 35% of patients and radiation in 16%. Prior to MIE, esophageal stents were inserted in 6%, feeding tubes (G or J tubes) in 3%, and previous open abdominal surgery had been performed in 25% of the patients. The majority of cases were completed using a minimally invasive three-hole approach. Reasons for conversion to open esophagectomy included dense pleural adhesions, bleeding from esophageal and intercostal vessels, and difficulty with an intrathoracic anastomosis. Open thoracotomy is also occasionally necessary in the setting of locally advanced tumors. In the initial 222 cases performed at this institution, mini thoracotomy was liberally performed in 8 of the first 15 patients, with only four additional thoracotomies utilized in the next 207 cases. Conversion to open laparotomy was performed in four patients due to dense abdominal adhesions. Overall, MIE was successfully completed in 206 patients (93%), with a 30-day operative mortality of 1.4% (N = 3). The reason for this trend is not established, though lower rates of respiratory and wound-related complications are evident when compared with the reports of standard open esophagectomy, which in turn may account for the lower mortality. The most frequent minor complication was atrial fibrillation (12%), followed by pleural effusion (6%), which was treated with bedside thoracentesis or pigtail catheter drainage. Major complications occurred in 32% of patients. The most common major complication was anastomotic leak (12%). Most anastomotic leaks were localized to the neck, and were managed conservatively. Pneumonia was the second most common major complication, occurring in 8% of patients. Vocal cord palsy (4%), chylothorax (3%), and gastric tip necrosis (3%) were rare,

---

Fig. 19.13. Excision of gastric tip following completion of esophagogastric anastomosis.

Fig. 19.14. Through a low transverse cervical incision, the esophagogastric specimen is removed and the gastric tube is advanced to the neck.
but serious, complications. Early Teflon or Gelfoam injection of the vocal cords in the setting of recurrent laryngeal nerve palsy improves swallowing function and lowers the risk of aspiration. Oncologic outcomes appeared comparable to published open series.

Our initial experience with minimally invasive Ivor–Lewis esophagectomy was reported in 2006 and included 50 patients. The initial 35 procedures included a planned mini thoracotomy, and the remaining 15 patients had a totally laparoscopic/thoracoscopic MIE. The anastomotic leak rate was 6% and pneumonia (10%) was only encountered in those patients who underwent mini thoracotomy. Median ICU length of stay was 1 day for the entire group. Patients who underwent mini thoracotomy had a significantly prolonged length of hospital stay (9 days) compared with those who underwent a total MIE (7 days).

We have now performed over 1,000 MIEs, with the Ivor–Lewis esophagectomy constituting our preferred minimally invasive approach. In our review of 1,011 patients undergoing MIE, 481 patients underwent three-hole MIE and 530 the Ivor–Lewis MIE approach. The operative mortality was 1.7% for the entire series (2.5% three-hole vs. 0.9% Ivor–Lewis). There were no intraoperative deaths. The frequency of conversion to open esophagectomy remained stable at 4.5%. Median ICU stay (2 days) and overall hospital length of stay (8 days) were similar between the two approaches. The median number of lymph nodes harvested was 21 (23.5 Ivor–Lewis vs. 19 three-hole; \( P < 0.001 \)). A significant reduction in vocal cord paresis/paralysis was noted in the Ivor–Lewis group when compared with the three-hole approach (8% vs. 1%; \( P < 0.001 \)). At a median follow-up of 20 months, the stage-specific survival was comparable to open series.

The early results of MIE compare favorably with the results of many series of open esophagectomies. Mortality rates of open esophagectomy from several of the largest open series range from 3% to 9.8%. In a highly publicized analysis of esophagectomy outcomes derived from the national Medicare claims database, published by Birkmeyer and coauthors, high-volume hospitals were found to have the lowest mortality (8.1%), with mortality exceeding 15% in medium- to low-volume centers. By comparison, 30-day operative mortality after MIE in our series was 1.7%. These data suggest that MIE can be performed safely with good results in an experienced center.

In one study comparing minimally invasive \( (N = 18) \) and open \( (N = 16) \) esophagectomy, Nguyen and coworkers found that the mean operative time (364 minutes), blood loss (297 ml), and length of intensive care unit stay (6 days) were decreased with MIE as compared with the open esophagectomy performed at the same institution. The incidence of respiratory complications (pneumonia, pulmonary embolism, respiratory failure) was similar between the MIE and open approaches. It should be emphasized that there are significant differences between the study groups in this retrospective comparison. The patients who underwent open esophagectomy had more advanced cancers. Additionally, the open operations were performed by four surgeons with variable experience, whereas the MIE procedures were performed by a single surgeon with expertise in minimally invasive esophageal surgery. The open operations were performed several years before the MIE procedures, so there may also have been differences in practice accounting for longer hospital stays.

Quality-of-life subjective assessments after MIE have been reported to be similar to preoperative values and population norms. In our series of 222 patients, the mean postoperative dysphagia score was 1.4 on a scale from 1 (no dysphagia) to 5 (severe dysphagia). Since reflux can be an issue after esophagectomy, heartburn severity was measured using the Health-Related Quality of Life Index (HRQOL). The mean heartburn score was 4.6 (on a scale from 0 to 45), which represents a normal (no reflux) score. SF36 scores were also measured and were not significantly different compared with age-matched normal values during follow-up.

In conclusion, MIE is a technically demanding procedure with a significant learning curve. Operative times typically decrease from 7 to 8 hours to 4 to 5 hours after performing 20 operations. Therapeutic outcomes compare quite favorably with most open series and are superior in many instances. Such encouraging results will serve to broaden the applicability of this technique to higher-risk patient groups such as the elderly and patients who have received prior neoadjuvant or endoscopic therapy (e.g., chemoradiation, stents). Prospective studies will be required to determine whether postoperative pain.
recovery time, and cost are improved. The Phase II Eastern Cooperative Oncology Group intergroup study (E2202) evaluating the safety profile of MIE has completed accrual, and results should be forthcoming in the near future. Until these results are available, the optimal surgical approach for each patient should be decided based on surgeon experience, tumor characteristics, and patient preference.

**SUGGESTED READINGS**

There is not another group in the country and perhaps in the world with greater experience in minimally invasive esophagectomy (MIE) than the Luketich group at the University of Pittsburgh. In this chapter they elegantly describe their technique as well as outcomes, which compare favorably with those reported for open procedures. As they correctly point out, there is a significant learning curve associated with this operation but the technique can be mastered especially by the surgeon experienced with open esophagectomy. The Pittsburgh group clearly favors the Ivor Lewis operation done via laparoscopy and thoracoscopy over a three-hole technique where the anastomosis is placed in the neck. Leak rates are lower when the anastomosis is placed within the chest and the incidence of recurrent nerve injury is negligible when dissection in the neck is avoided.

I am not yet convinced that the morbidity or mortality results with MIE are any better than those achieved by an experienced group performing standard open esophagectomy. The length of stay does not appear to be significantly different and frankly I would not expect it to be. The length of time that it takes to heal an anastomosis and start a patient on oral intake should be the same no matter how the resection is performed and discharge really cannot occur until the anastomosis is demonstrated to be intact and the patient is eating. Whether or not there is a difference in postoperative pain still remains to be determined although intuitively one would expect those undergoing MIE to have less pain without a big abdominal incision and a rib spreading thoracotomy. That said, I have been convinced for years that I have been doing a MIE and it is called a transhiatal esophagectomy, an operation that involves no thoracic incision, not even small ones. It is likely that those completing cardiothoracic residencies today may have more experience with the MIE operation described by Luketich and colleagues than with the transhiatal approach. In addition MIE using the robot may further enhance the capabilities of the minimally invasive approach with the enhanced three-dimensional visualization and increased technical capability provided by the robotic arms. But as I have repeatedly stated the complete esophageal surgeon must have the capability to perform an array of approaches since there are so many variations in presentation that are encountered. One approach does not fit all. MIE clearly adds to the armamentarium of the esophageal surgeon and it behoves one interested in this area to master the procedure.

LRK
The diagnosis and treatment of esophageal motility disorders can be an important part of a thoracic surgeon’s practice. The majority of patients with esophageal motility disorders are referred to surgeons following a primary assessment by a gastroenterologist. The patients are commonly on various medications and have undergone multiple endoscopies and dilatations. The effects of these treatments may be of some benefit but the patient’s symptoms remain and a more definitive solution is desired. It is crucial for the thoracic surgeons prior to surgery to validate the accuracy of the patient’s diagnosis. To do so, they must understand esophageal physiology, be able to perform a thorough esophageal assessment, and determine the best treatment option.

Since the last edition of this book, there has been a shift in the surgical approach to esophageal motility disorders. A left thoracotomy, once the standard approach to perform a Heller myotomy, has been replaced by the laparoscopic approach. Similarly, sophisticated diagnostic tools have been developed, such as high-resolution manometry, esophageal impedance, and 48-hour Bravo pH capsule. In this chapter, we will review the diagnosis and treatment of the primary and secondary esophageal motility disorders. We will focus on the diagnostic assessment and the use of endoscopic, minimally invasive, and open surgical therapy.

CLASSIFICATION OF ESOPHAGEAL MOTILITY DISORDERS

1. Primary esophageal motility disorders (absence of extra esophageal causes)
   a. Achalasia
   b. Diffuse esophageal spasm
   c. Nutcracker esophagus
   d. Hypertensive lower esophageal sphincter
   e. Ineffective esophageal motility

2. Secondary esophageal motility disorders (due to extra esophageal causes)
   a. Collagen vascular disease (scleroderma, polymyositis, dermatomyositis, systemic lupus)
   b. Neuromuscular disease (myasthenia gravis)
   c. Endocrine and metabolic disorders

ACHALASIA

Definition, Prevalence, and Natural History

Achalasia is a primary esophageal motility disorder that can affect the esophageal body, lower esophageal sphincter, and stomach. It is characterized by the absence of peristaltic contractions in the esophageal body, a hypertensive lower esophageal sphincter, complete or nearly complete loss of the lower esophageal sphincter relaxation on swallowing and, an elevation of esophageal luminal pressure above gastric baseline pressure. Some patients may also have delayed gastric emptying. The latter can occur years after the onset of the disease.

The frequency of the disease in the western world is one per 100,000 population per year with geographic pockets of higher incidences. There are two peaks in the occurrence of the disease, one between ages 20 and 40 and the other between 60 and 70. If left untreated, achalasia will cause a dilated esophagus from the accumulation of liquid within the lumen. The weight of the retained liquid column causes the loss of the normal esophageal axis and the formation of a sigmoid esophagus. Eventually, the patient loses the ability to drink water or take solid nourishment. In the past, this resulted in the death of the patient from dehydration and starvation. Patients with achalasia have higher risk for squamous cell carcinoma of the esophagus.

Vigorous Achalasia

A subgroup of patients with achalasia have isolated simultaneous segmental contractions in the esophageal body of high amplitude (> 180 mmHg). These patients present with chest pain in addition to dysphagia. These patients do not do as well after surgical therapy due to the persistence of chest pain in about 50% of those operated on.

Etiology and Symptoms

The cause of achalasia is unknown. Hereditary, degenerative, autoimmune, and viral infections have been identified as possible etiologies. The most common symptom is dysphagia, which is reported in 94% of patients, followed by regurgitation in 76% and chest pain in 41%.

Up to half of the patients may complain of heartburn from esophageal distension, acidic fermentation of retained food, or delayed clearance of rare reflux episodes.

Diagnosis

A videosophagram, an esophageal motility study, and an upper endoscopy should be obtained in patients suspected of having achalasia. Computed tomography (CT) scan and pH monitoring are selectively used.

Videoesophagram

In patients with early achalasia, the esophagus is normal in diameter and peristalsis is absent. The distal esophagus is characterized by a smooth tapering of the barium column resembling a bird’s beak. As the disease progresses, the esophagus becomes more dilated and tortuous. Retained food and saliva collect within the esophageal lumen and form an air-fluid level when the patient is in the upright position (Fig. 20.1). A gastric air bubble is typically absent.

Upper endoscopy

In patients with achalasia, upper gastrointestinal endoscopy shows a dilated
Early Achalasia

Advanced Achalasia

**Fig. 20.1.** Barium esophagram in patients with early and advanced achalasia. In early achalasia, the esophagus is dilated, the axis remains straight, peristalsis is absent, and the esophagus is narrowed at the level of the diaphragm suggesting a "bird’s beak" deformity. In advanced achalasia, the esophagus is extensively dilated, the axis is deviated, usually to the right, and a "bird’s beak" deformity is commonly seen at the level of the diaphragmatic hiatus.

esophagus containing foamy saliva and retained food (Fig. 20.2). The gastro-esophageal junction is closed but allows a 9-mm endoscope to be pushed through the junction with minimal but definite resistance. Rarely is balloon dilation required to facilitate the passage of the scope. Pseudoachalasia can occur secondary to esophageal obstruction from a malignant lesion at the level of the gastroesophageal junction. Upper endoscopy usually can exclude this possibility, but occasionally the diagnosis can be difficult due to normal mucosa that overlies a submucosal tumor. A CT scan usually resolves the issue. The upper gastrointestinal endoscopy should be performed by the operating surgeon prior to the day of the surgery. If performed immediately prior to surgery, the upper abdominal viscera can become distended and obstruct the laparoscopic image.

**Esophageal Manometry**
The gold standard for the diagnosis of achalasia is the complete or nearly complete loss of the lower esophageal sphincter relaxation in response to wet swallows and the absence of peristalsis in the esophageal body on esophageal manometry (Fig. 20.3). A hypertensive lower esophageal sphincter is present in less than half of the patients. Commonly, there is an elevated esophageal baseline luminal pressure reflecting outflow resistance. Patients with vigorous achalasia have in addition isolated segmental contractions of high amplitude (> 180 mmHg; Fig. 20.4).

**Computed Tomography Scan**
A CT scan is not necessary except when pseudoachalasia is suspected, and the gastroesophageal junction needs to be imaged to identify a mass compressing the esophagus.

**pH Monitoring**
pH monitoring is performed when the diagnosis of achalasia is questionable and gastroesophageal reflux disease is suspected. It is not uncommon to confuse the two entities. Achalasia patients can complain of heartburn from esophageal distension, acidic fermentation of retained food, or delayed clearance of rare reflux episodes. To exclude gastroesophageal reflux disease, pH monitoring should be performed. The pH tracing must be carefully analyzed to distinguish the episode of gastroesophageal reflux from long periods of low pH secondary to fermentation of retained food or episodes of rare reflux that clears slowly from the esophagus.

**Treatment**
The goal of therapy for achalasia is deceptively simple: to relieve dysphagia by reducing esophageal outflow resistance without causing unimpeded reflux of the gastric juice. To achieve this goal is more difficult than it sounds.

**Nonsurgical Treatment**
**Botox Injection**
Botulinum toxin inhibits the calcium-dependent release of acetylcholine from nerve endings involved in the relaxation of the lower esophageal sphincter. It is therapeutically effective in relieving dysphagia in about 85% of patients. Over a period of 6 months, the symptoms recur in more than 50% of the patients possibly because of regeneration of the affected receptors. Patients older than 60 are likely to have a sustained response lasting for 1 to 5 years.

A Heller myotomy after Botox injection can be difficult and less effective.
because of submucosal scar formation. The fibrotic reaction can obliterate the anatomical plane between the mucosa and the muscular layer of the esophagus. This increases the risk of mucosal perforation when performing the myotomy. For this reason, Botox injections are used only in high-risk elderly patients with significant comorbidities.
Pneumatic Balloon Dilation
Pneumatic balloon dilation of the lower esophageal sphincter is the most effective nonsurgical treatment for achalasia. A special balloon, used to perform dilatation, is inflated to a diameter of 30 to 40 mm or a circumference of 90° to 120°. The procedure is monitored under fluoroscopy, and the balloon is commonly filled with liquid contrast for a better visualization during inflation. The waist of the balloon is positioned at the level of the hypertrophied lower esophageal sphincter and is inflated to a diameter of 30 mm. A follow-up procedure can be performed if dysphagia persists. This is usually done by inflating the balloon to a diameter of 40 mm. The procedure is associated with a 1.6% to 4% risk of esophageal perforation. Predictors of a poor outcome are an age <40 and a lower esophageal sphincter pressure >10 mmHg 3 months after the procedure.

Surgical Treatment
Heller Myotomy
The most effective and durable treatment for achalasia is a Heller myotomy. Initially, this procedure was performed trans-thoracically either via a thoracotomy or
thoracoscopy. Today, the procedure is universally performed by laparoscopy. Critical steps of the operation as done by us involve performing a left lateral myotomy in line with the greater curvature of the stomach, starting at the apex of the diaphragmatic esophageal hiatus dividing the esophageal muscle, all the oblique fibers at the angle of His and extending the myotomy 3 cm beyond the gastroesophageal junction onto the stomach. The loss of esophageal axis and a long duration of symptoms are predictors of a poor outcome.

**Fundoplication after Heller Myotomy**

After Heller myotomy, 40% to 60% of patients have gastroesophageal reflux. For this reason, it is recommended that a partial fundoplication should be added. A prospective randomized trial of myotomy alone or myotomy plus Dor fundoplication showed a reduction in postoperative reflux from 48% to 9%, respectively. In contrast, a more recent randomized trial on the degree of partial fundoplication, that is a 180-degree Dor anterior fundoplication versus a 270-degree Toupet posterior fundoplication, did not show a difference in reflux protection. The advantage of a Toupet fundoplication is the retraction of the edges of the myotomy, potentially reducing reapproximation and healing of the myotomized muscle edges together resulting in recurrent dysphagia. The disadvantages are the need to dissect posterior to the esophagus with the potential to damage the posterior vagus nerve and leaving the mucosa at the myotomy site uncovered. In contrast, the Dor fundoplication does not require posterior dissection and covers the mucosa at the myotomy site.

**Surgical Technique of Heller Myotomy and Dor Fundoplication**

The patient is placed on the operating table and positioned in the reverse Trendelenburg with the lower extremities spread apart in leg holders. A 1.5-cm incision is made just to the left of the midline, two-third the distance between the xiphoid and the umbilicus. An 11-mm Opti-port and a zero-degree scope are used to obtain access into the abdominal cavity under direct vision. The zero-degree scope is exchanged for a 30 degree scope. Under direct vision, a 12-mm multipurpose port is placed in the left upper quadrant, a 5-mm retraction port in the left lower quadrant, a 5-mm dissection port in the right upper quadrant, and a 5-mm port is used to create a channel into the abdomen just below the xiphoid for the insertion of the liver retractor (Fig. 20.5). The liver retractor supplied with the “Iron Intern” is passed through the channel, placed under the left lobe of the liver, elevated and retracted to the right to expose the esophageal diaphragmatic hiatus (Fig. 20.6).

The superior upper third of the gastric greater curvature is mobilized by dividing the short gastric vessels. The posterior fundus is dissected off the lateral surface of the left crus. The left lateral wall of the esophagus is separated from the left crus and the esophagus is mobilized from the crural decussation up to the apex of the diaphragmatic hiatus and into the inferior mediastinum.

The gastroesophageal fat pad is dissected off the esophagus in a left-to-right direction allowing the right side of the fat pad to remain attached. A right-angle instrument is passed through the right upper quadrant dissection port and a small window is created in the base of the mobilized gastroesophageal fat pad at the point where the stomach flares from the tubular esophagus. A vessel loop is passed through the right upper quadrant dissection port, guided through the window and is brought back out through the right upper quadrant port site. The port is removed to free the vessel loop from the lumen of the port and the port is reinserted adjacent to the vessel loop. The esophagus is rotated to the right by retraction of the vessel loop so that the greater curvature of the stomach is in an anterior position (Fig. 20.7) of the stomach.

The myotomy is performed on the left lateral surface of the esophagus in line with
Section I: General Thoracic Surgery

Fig. 20.7. The gastroesophageal junction identified by the point where the stomach flares from the tubular esophagus. Retraction on the vessel loop rotates the esophagus to the right so that the left lateral surface of the esophagus is exposed.

The greater curvature of the stomach. It extends from the apex of the hiatus down to the gastroesophageal junction and along the greater curvature of the stomach for 3 cm. Electrocautery is used to mark the site of proposed myotomy (Fig. 20.8). The myotomy is started by using a laparoscopic curved dissector to gently separate the longitudinal and circular muscular layers and identify the mucosa. This part of the operation must be meticulously performed. Once all the muscular fibers are separated, the mucosa bulges out. From this point, the myotomy is performed superiorly and inferiorly. In the superior direction, the esophageal muscle is divided by electrocautery using scissors up to the apex of the diaphragmatic hiatus. In the inferior direction, a laparoscopic hook is used to extend the myotomy down to the gastroesophageal junction and for 3 cm along the greater curvature of the stomach. The esophageal muscle is usually thick and white in appearance. Any remaining small septae on the mucosal surface are divided (Fig. 20.9). A Kittner dissector is used to push back the edges of the myotomized esophageal muscle to widen the myotomy and create a lip of the myotomized muscle at the edge of the myotomy. If persistent bleeding occurs from the muscle edges, it can be stopped with electrocautery; in doing so, care should be taken not to cauterize the mucosal surface.

An upper endoscopy is performed to confirm the extent of the myotomy and to assess for a mucosal leak. During the endoscopy the stomach should readily distend with insufflation of air into the esophagus. The scope should pass easily into the stomach. The stomach is deflated in preparation for a Dor fundoplication.

A Dor fundoplication is placed over the myotomy site. In doing so, the exposed gastric mucosa in the myotomized portion of the stomach is opposed to the exposed esophageal mucosa in the lower portion of the esophageal myotomy. This mucosal to mucosal apposition constructs a thin frenulum between the stomach and the esophagus eliminating outflow resistance and functions as a flap valve to oppose regurgitation.

To construct the flap valve mentioned above, the Dor fundoplication is started inferiorly by placing an interrupted stitch through the left crus at the decussation and the myotomized muscle at the level of the gastroesophageal junction. This begins the folding of the stomach against the esophagus. The second stitch is placed through the lip of the myotomized stomach, through the left crus 1 cm cephalad to the prior stitch and through the left lip of the myotomized esophageal muscle.

Subsequent stitches are placed through the serosa of the stomach, the left crus, and the left lip of the myotomized esophageal muscle at 1 cm intervals until the apex of the myotomy at the diaphragmatic esophageal hiatus is reached. These stitches are placed so that the greater curvature rolls superiorly in line with the middle of the esophageal myotomy site (Fig. 20.10). At the apex of the diaphragmatic esophageal hiatus, a stitch is placed through the stomach, through the apex of the diaphragmatic hiatus, through the esophagus above the myotomy site, back through the apex of the diaphragmatic hiatus, 1 cm to the right, and through the apex of the rolled up stomach and tied. This anchors the superior end of the myotomy and the Dor partial fundoplication to the diaphragm and avoids the formation of the esophageal diverticulum in the apex of the myotomy. The stitches are continued down on the right side, sutureting the stomach to the right lip of the esophageal myotomy. The last stitch is placed at the level of the gastroesophageal junction in line with the initial stitch placed on the left in the same position. There should be a good distance between the two stitches so that the partial fundoplication has the shape of a triangle.

Fig. 20.8. Laparoscopic view of the location of the myotomy marked by the electrocautery down the left lateral surface of the esophagus and along the greater curvature of the stomach. The esophagus has been rotated to the right by the retraction of the vessel loop (not shown).
Fig. 20.9. Laparoscopic view of a complete myotomy extending from the apex of the esophageal diaphragmatic hiatus, across the gastroesophageal junction, and down 3 cm along the greater curvature of the stomach.

Fig. 20.10. Laparoscopic view showing the stomach attached to the left side of the myotomy form the gastroesophageal junction up to the apex of the esophageal hiatus. The mucosa of the gastric myotomy site has already been opposed to mucosa of the esophageal myotomy site.

At this point in the operation, a second endoscopy is performed to assure easy access into the stomach and to rule out any torsion of the repair. A retroflexed view of the gastroesophageal junction should show an edematous but well-formed Dor fundoplication with a frenulum formed by the apposition of the gastric and the esophageal mucosa in the lower portion of the myotomy site.

The vessel loop is removed, and the stomach and esophagus are rolled back to their normal anatomic position. The Dor fundoplication lies in the left lateral position, covers 180 degrees of the esophageal surface, and does not distort the normal plane of the stomach (Fig. 20.11). The remnants of the short gastric vessels remain in their normal anatomical position with no evidence of torsion or twist of the stomach (Fig. 20.12). A nasogastric tube is not placed in the stomach as patients with achalasia rarely swallow excessive amounts of air. The steps of the laparoscopic myotomy and Dor fundoplication are summarized in Table 20.1.

The patient is hospitalized the night of surgery. The day after surgery, the patient is given a clear liquid breakfast and a full liquid lunch. If taken well, the patient is discharged home. The patient is instructed to continue on a full liquid diet for 2 weeks. A clinical evaluation is then performed and the patient, if doing well, is advanced to a soft diet with instructions to progress to a regular diet as tolerated.

Management of a Failed Heller Myotomy
A failed Heller myotomy is suspected when a patient has persistent or recurrent dysphagia after the procedure.

Persistent dysphagia is usually due to one of the following technical problems:

1. The myotomy may have been too short or fibers of the lower esophagus were left intact. It only takes a few intact fibers to cause dysphagia.
2. The Dor fundoplication may be twisted, causing narrowing of the gastroesophageal junction.
3. An injury to the esophageal mucosa by the electrocautery may have caused a stricture.

Recurrent dysphagia occurring after a symptom-free interval can be due to the following:

1. Reapproximation and healing of the myotomized muscle.
2. Poor transit of medications causing a distal esophageal drug stricture.
3. Formation of an esophageal stricture from severe gastroesophageal reflux.
4. The presence of an esophageal malignancy.

A thorough evaluation must be performed in patients with recurrent dysphagia and includes the reports of the initial detailed history, review of the operative report and the reports of the initial barium swallow, upper endoscopy, esophageal manometry, and pH monitoring. The treatment options depend on the etiology of the dysphagia. Pneumatic dilatation can be used to widen a narrowed esophagus caused by the healing of the myotomy site or a stricture from severe reflux esophagitis. The latter is usually of temporary benefit and the former may require a redo-myotomy for relief. A cautery-induced nonreflux stricture can be managed by a mucosal plasty. Patients with severe unrelenting dysphagia from a persistent or recurrent reflux stricture usually require a vagal-sparing mucosal stripping esophagectomy (described further in this chapter).

Peroral Endoscopic Surgical Myotomy
In 2009, Haru Inoue described an endoscopic Heller myotomy that has engendered considerable enthusiasm. This new endoscopic technique is performed under general anesthesia. A small mucosal opening is made...
in the mid-to-distal esophagus and a submucosal tunnel is developed. The tunnel is extended down across the gastroesophageal junction and onto the stomach. A myotomy of the circular muscle fibers is performed. The length of myotomy is about 8 cm, 6 cm in distal esophagus, and 2 cm beyond to the gastroesophageal junction in the stomach. The small opening in the esophageal mucosa is closed with an endoscopic clip. A smooth passage of an endoscope through the gastroesophageal junction is confirmed at the end of the procedure. Early reports on the outcome of this procedure show a significant improvement in the complaint of dysphagia and a reduction in the resting lower esophageal sphincter pressure. To date, no serious complications of the procedure have been reported. Further studies on long-term improvement of the dysphagia, the degree of the postoperative reflux, and comparison with traditional therapies are expected before wider use of this technique is recommended.

**Esophagectomy for Treatment of Achalasia**

If the axis of the esophagus is straight, an esophagomyotomy will provide good relief of dysphagia and will allow the esophagus to empty by gravity. In patients with end-stage achalasia who have a sigmoid-shaped megaesophagus of greater than 10 to 11 cm in diameter (Fig. 20.13) retention of food and saliva can occur in the tortuous segment. In these patients, an esophagomyotomy is likely to be of little benefit.

In such patients, we recommend that the esophagus be removed. Our preferred technique of removal is a mucosal stripping vagal-sparing esophagectomy. This procedure was developed to avoid the need for mediastinal dissection and the morbidities associated with standard esophagectomy by preserving the vagal nerves. The procedure straightens the esophageal axis to improve emptying.

**Steps of Mucosal Stripping Vagal-Sparing Esophagectomy**

Mucosal stripping vagal-sparing esophagectomy removes the esophageal mucosa while preserving the esophageal muscular wall and the vagal plexus. By these means, it avoids mediastinal bleeding from the enlarged arteries associated with a megaesophagus and maintains vagal integrity to eliminate postoperative dumping and diarrhea. Gastrointestinal continuity is re-established with a gastric conduit constructed after performing a highly selective gastric vagotomy along the lesser curvature of the stomach.

The procedure is started by performing an upper midline abdominal incision. The right and left vagal nerves are identified, circled with a tape, and retracted to the right. A highly selective proximal gastric vagotomy is performed along the lesser curve of the stomach from the incisura to the gastroesophageal junction. The left gastric artery is left intact. The gastric conduit is left intact. The gastric conduit is constructed by using a GIA stapler to form a tube, 3 cm wide, along the greater curvature of the stomach.

A neck incision is made along the anterior border of the left sternocleidomastoid muscle and the strap muscles are exposed. The omohyoid muscle is divided at its pulley, and the sternohyoid and sternothyroid muscles are divided at their manubrial insertion. The left carotid sheath is retracted laterally and the thyroid and trachea medially. The left inferior thyroid artery is ligated laterally as it passes under the left common carotid artery. The left recurrent laryngeal nerve is identified and protected. The esophagus is dissected circumferentially from the left neck with the scissors pointed in the direction of the apex of the right chest, to avoid injury to the right recurrent laryngeal nerve. The esophagus is encircled with a Penrose drain.

Returning to the abdomen, the gastroesophageal junction is divided with a GIA stapler. A 1 cm opening in the mid-portion
Laparoscopic Heller myotomy

1. Place the patient in the reverse Trendelenburg position with the lower extremities spread apart in leg holders
2. Insert five laparoscopic ports
3. Take down of the short gastric vessels along the upper third part of the greater curvature of the stomach
4. Separate the left lateral wall of the esophagus from the left crus and mobilize the left lateral wall of the esophagus from the decussation to the apex of the diaphragmatic esophageal hiatus
5. Dissect the gastroesophageal fat pad from the esophagus in a left-to-right direction
6. Place a vessel loop through a small window created in the base of the fat pad and retract the gastroesophageal junction to the right
7. Mark the myotomy site using electrocautery from the apex of the diaphragmatic esophageal hiatus across the gastroesophageal junction and 3 cm down the greater curvature of the stomach.
8. Perform the myotomy with electrocautery using scissors in the superior direction up to the level of the diaphragmatic hiatus and a laparoscopic hook in the inferior direction down to 3 cm beyond the gastroesophageal junction along the greater curvature of the stomach.
9. Free the edges of the myotomy from the mucosa
10. Perform upper endoscopy to assess the extent of the myotomy and presence of a leak
   1. The stomach should easily insufflate from the esophagus
   2. The scope should pass without resistance into the stomach

Laparoscopic Dor fundoplication

1. Start inferiorly by placing an interrupted stitch through the left crus at the decussation and the myotomized muscle at the level of the gastroesophageal junction to fold the stomach against the esophagus
2. Place the second stitch through the lip of the myotomized stomach, through the left crus 1 cm cephalad to the prior stitch, and through the left lip of the myotomized esophageal muscle
3. Place the subsequent stitches through the serosa of the stomach, the left crus, and the left lip of the myotomized esophageal muscle at 1 cm intervals until the apex of the myotomy at the diaphragmatic esophageal hiatus. The greater curvature should roll up in line with the middle of the esophageal myotomy site
4. Place the apical stitch by passing the needle through the stomach, the diaphragmatic hiatus, the esophagus above the myotomy site, the diaphragmatic hiatus 1 cm to the right, the stomach, and tie
5. Continue the stitches down on the right side, suturing the stomach to the right lip of the esophageal myotomy
6. Place the last stitch at the level of the gastroesophageal junction in line with the initial stitch placed on the left in the same position. There should be a good distance between the two stitches so that the partial fundoplication has the shape of a triangle
7. Perform an upper endoscopy to assess the ease of access to the stomach and the configuration of the fundoplication

Returning to the neck, the muscle on the left lateral surface of the cervical esophagus is excised over 180 degrees of the esophageal circumference to expose the mucosa. The mucosa is circumferentially separated from the remaining intact esophageal muscle and divided transversally. The thin tip of the stripper is exchanged for a mushroom head, and the esophageal mucosa is secured tightly around the stripping cable using an endo-loop and umbilical tape. Sufficient length of one limb of the umbilical tape should remain to use as a trailer.

Returning to the abdomen, the stripper is pulled in an inferior direction to strip the esophageal mucosa from the muscular wall of the dilated esophagus. The vagus nerves remain intact along with the esophageal muscular wall. The muscular tube is inspected for bleeding and if present, a lap pad soaked with epinephrine diluted 1:10,000 is pulled through to pack the muscular tunnel to stop the bleeding. A Foley catheter containing 90 cm³ of fluid in the balloon is used to dilate the muscular tunnel. The gastric conduit is pulled up through the muscular tunnel into the neck and anastomosed to the cervical esophagus.

The procedure avoids a thoracotomy as well as the risk of severe bleeding that can occur in these patients with a transhiatal resection. The placement of the gastric conduit within the native esophageal muscular tube straightens the esophageal axis.

**DIFFUSE ESOPHAGEAL SPASM**

**Definition**

Diffuse esophageal spasm is a primary esophageal motility disorder occurring in about 3% to 5% of patients with esophageal motility disorders. It is characterized...
by >20% simultaneous contractions in the esophageal smooth muscle and symptoms of dysphagia and chest pain. It differs from achalasia in that the lower esophageal sphincter relaxes on swallowing.

Etiology and Symptoms
The cause of diffuse esophageal spasm is uncertain. It is seen in all ages but most commonly in patients >50-year old. The symptoms of dysphagia and chest pain vary in intensity from mild to severe, last for seconds to minutes, are precipitated by solids or liquids, and can occur during the fasting state.

Diagnosis

Videoesophagram
The videoesophagram in patients with diffuse esophageal spasm can show a "corkscrew" esophagus (Fig. 20.14) but due to the intermittent nature of diffuse esophageal spasm, the finding is only seen in 30% of patients.

Esophageal Manometry
The primary motility abnormality in diffuse esophageal spasm is the occurrence of simultaneous contractions following more than 20% of the wet swallows (Fig. 20.15). Contrary to achalasia, normal peristaltic waves are always seen between episodes of simultaneous contractions. The lower esophageal sphincter is usually normotensive but can be hypertensive and, in contrast to achalasia, relaxes normally on swallowing. Other less common manometric findings are long duration, multipeaked contractions, and nonswallow-induced spontaneous contractions.

pH Monitoring
Some patients with gastroesophageal reflux disease can masquerade as diffuse esophageal spasm. Esophageal pH monitoring is helpful to identify these patients.

Treatment

Nonsurgical Treatment
Smooth-muscle relaxants and anticholinergics can decrease high-amplitude contractions but do not consistently relieve chest pain. Pneumatic dilation or injection of Botulinum toxin helps some patients with diffuse esophageal spasm, particularly those with dysphagia, a hypertensive lower esophageal sphincter and documented delay in the esophageal emptying on barium swallow.

Surgical Treatment
Symptomatic patients with diffuse esophageal spasm who do not respond to medical therapy can be considered for surgical therapy. The key to success of surgical therapy is careful analysis of the percentage of pathologic simultaneous nonperistaltic esophageal contractions. If the patient has more than 75% pathologic simultaneous nonperistaltic esophageal contractions, a myotomy is likely to improve the dysphagia. If the patient has <75% pathologic simultaneous nonperistaltic esophageal contractions, a myotomy is less likely to improve the dysphagia and may make the dysphagia worse by destroying the existing normal peristaltic contractions. In principle, a myotomy is more likely to improve dysphagia and less likely to add to the degree of the dysphagia when the number of normal peristaltic contractions is below 25%.

The surgical treatment of diffuse esophageal spasm is similar to that of achalasia except for the length of the myotomy. In diffuse esophageal spasm, the myotomy starts above the level on the esophagus where the simultaneous nonperistaltic esophageal contractions occur on manometry and extend down the esophagus across the lower esophageal sphincter and 2 cm over the stomach. Sparing the lower esophageal sphincter from the myotomy has been reported to result in esophageal obstruction with the accumulation of liquid and food above the sphincter and the potential for esophageal rupture.

NUTCRACKER ESOPHAGUS

Definition
Nutcracker esophagus is a primary esophageal motility disorder characterized by high amplitude peristaltic esophageal contractions (>180 mmHg) of long duration (>6 seconds). These contractions are usually asymptomatic but can be associated with chest pain. Dysphagia is uncommon.

Etiology and Symptoms
The etiology of nutcracker esophagus is unknown even though it is the most common motility disorder reported. Consequently, when not associated with symptoms it may be a normal variant of esophageal contractility, that is an amplitude above the 95% threshold used to make the diagnosis.

Diagnosis

Videoesophagram
The videoesophagram in patients with nutcracker esophagus is commonly normal.

Esophageal Manometry
Esophageal manometry in patients with nutcracker esophagus is characterized by peristaltic waves of high amplitude (>180 mmHg) and prolonged duration (>6 seconds) (Fig. 20.16). Lower esophageal sphincter can be normotensive or hypertensive but shows complete relaxation with wet swallows.

pH Monitoring
Some patients with gastroesophageal reflux disease can masquerade as nutcracker esophagus. Esophageal pH monitoring is helpful to identify these patients. If gastro-esophageal reflux disease is present, the motility pattern is secondary rather than primary, and therapy should be directed toward the correction of the abnormal reflux.

Treatment

Nonsurgical Treatment
Patients with nutcracker esophagus are treated only if symptoms are present.
Smooth-muscle relaxants and anticholinergics have been tried with minimal benefit. Pneumatic dilation or Botulinum toxin is of some help but the benefit is unpredictable.

**Surgical Treatment**

Surgery may be beneficial to a very select group of patients with nutcracker esophagus who have dysphagia and a hypertensive lower esophageal sphincter. In this situation, a myotomy of the lower esophageal sphincter may improve the dysphagia. It is unlikely that the esophageal body abnormality is contributing to the symptom of dysphagia and should be spared of any surgical intervention.
HYPERTENSIVE LOWER ESOPHAGEAL SPHINCTER

Definition

Hypertensive lower esophageal sphincter is a primary esophageal motility disorder occurring in 7.2% of the patient population referred for motility studies. The diagnosis is made by manometry with the measurement of an abnormally high pressure in the lower esophageal sphincter that completely relaxes. Hypertensive lower esophageal sphincter can occur as an isolated condition or in association with gastroesophageal reflux disease, a paraesophageal hiatal hernia, an esophageal epiphrenic diverticulum, or nutcracker esophagus.

Etiology and Symptoms

Patients with hypertensive lower esophageal sphincter are a heterogeneous group with regard to symptoms and etiology. Symptoms may be caused by the motor abnormality in the primary form of the disease, or, in its secondary form, by gastroesophageal reflux, the altered geometry of the cardia that occurs with a paraesophageal hernia, an epiphrenic diverticulum, or a nutcracker esophagus. Dysphagia and chest pain that can masquerade as heartburn are the most common symptoms in patients with primary disease. Of those who complain of heartburn only 26% will have increased esophageal acid exposure on pH monitoring. This indicates that those symptomatic patients with normal esophageal acid exposure could be easily misdiagnosed as gastroesophageal reflux disease.

Diagnosis

Esophageal manometry is used to identify patients with hypertensive lower esophageal sphincter. The manometric definition of a hypertensive lower esophageal sphincter varies among motility laboratories and depends on the method used to read the lower esophageal sphincter pressure. If the pressure is measured at the peak of the diaphragmatic excursion, a pressure around 45 mmHg is usually the threshold, above which the sphincter is considered to be hypertensive. If the pressure is measured at the respiratory inversion point, where the effect of the diaphragmatic movement is minimal, then 26 mmHg is the threshold. Patients with primary hypertensive lower esophageal sphincter have higher sphincter pressures compared with those with secondary disease.

The criteria used in our motility laboratory to diagnose a patient with primary hypertensive lower esophageal sphincter require the following:

1. Elevated lower esophageal sphincter pressure at rest (mean pressure >26 mmHg)
2. Complete relaxation of the lower esophageal sphincter on swallowing (residual pressure <8 mmHg)
3. Peristaltic esophageal contractions of normal amplitude in the body of the esophagus.

Treatment

Nonsurgical Treatment

Medical management of the primary hypertensive lower esophageal sphincter is largely limited to drugs like nifedipine or sildenafil, and botulinum toxin to reduce lower esophageal sphincter pressure. Often, transient manometric improvement occurs with these drugs but is not associated with an equivalent clinical improvement. Dilatation has been tried with disappointing results. Acid suppression therapy relieves reflux symptoms, but their effect on dysphagia and chest pain is minimal.

Surgical Treatment

The surgical approach to a symptomatic patient with hypertensive lower esophageal sphincter is tailored based on the patient’s clinical findings. In symptomatic patients with primary hypertensive lower esophageal sphincter, a myotomy of the lower esophageal sphincter is done. Like in achalasia a Dor fundoplication is added to prevent reflux. In patients with secondary disease, that is hypertensive lower esophageal sphincter associated with gastroesophageal reflux disease, or a paraesophageal hiatal hernia, a Nissen fundoplication is performed. We have shown in this situation that a Nissen fundoplication, without a myotomy of the lower esophageal sphincter, relieves the patient’s heartburn, dysphagia, and chest pain. In symptomatic patients with hypertensive lower esophageal sphincter and an epiphrenic diverticulum, the diverticulum is resected and a myotomy is done from the level of the diverticulum across the lower esophageal sphincter and down to the stomach for about 2 to 3 cm and a Dor fundoplication is added. In symptomatic patients with hypertensive lower sphincter and nutcracker esophagus, a myotomy is limited to the lower esophageal sphincter.

INEFFECTIVE ESOPHAGEAL MOTILITY DISORDER

Definition

Ineffective esophageal motility is defined by a >30% frequency of low amplitude contractions <30 mmHg in the distal esophagus following wet swallows.

Etiology and Symptoms

Ineffective esophageal contractions in the esophageal body are seen in patients with gastroesophageal reflux disease and are thought to be due to inflammatory damage of the esophageal muscle. Heartburn and regurgitation are common symptoms. Dysphagia is usually mild but when severe, suggests an anatomical problem such as esophagitis or a peptic stricture.

Treatment

Nonsurgical Treatment

The nonsurgical treatment consists of acid suppression therapy for the gastroesophageal reflux disease.

Surgical Management

The most effective surgical procedure to treat gastroesophageal reflux disease is a Nissen fundoplication. A well-formed Nissen fundoplication can impose an esophageal outflow resistance up to 20 mmHg without producing dysphagia in patients with normal esophageal motility. If a patient has global peristaltic esophageal contractions <20 mmHg in the distal third of the esophagus, then a Nissen fundoplication is likely to result in dysphagia and partial fundoplication should be done. If an antireflux procedure is performed early in the disease, the inflammation in the esophageal body resolves along with improvement in the amplitude of esophageal contractions, and the dysphagia will also improve over time. Late in the disease, the muscle damage may be irreversible and the esophageal motility is unlikely to improve. In this situation, the combination of global contractions of <20 mmHg in the distal esophagus and the presence of a partial fundoplication is likely to result in dysphagia. If the dysphagia is severe, the patient is likely to have endstage reflux disease and a vagal-sparing esophagectomy might be a better choice.

Scleroderma

Definition

Progressive systemic sclerosis, known as scleroderma, is the most common
secondary esophageal motility disorder and the most common collagen vascular disease affecting esophageal function. The disease is characterized by the fibrosis of small arteries and arterioles causing ischemic injury and fibrosis of the organ involved. There is deposition of collagen throughout the body but most commonly seen in the skin, lungs, kidneys, and gastrointestinal tract. The esophagus is the most commonly affected portion of the gastrointestinal tract. Patients with esophageal involvement usually develop gastroesophageal reflux disease manifested by heartburn or dysphagia within 2 years of their diagnosis of scleroderma. The reflux disease is often severe and complications such as persistent erosive esophagitis, long-segment strictures, and Barrett’s metaplasia can develop. The mechanism of reflux in scleroderma patients is a destroyed lower esophageal sphincter that allows the reflux of the gastric juice, and an aperistaltic esophagus that is unable to clear the refluxed gastric juice. Gastric dysmotility is frequent in scleroderma and can result in delayed gastric emptying which contributes to the reflux problem. Further, scleroderma patients have impaired salivary production and are unable to chemically neutralize the refluxed gastric juice by swallowing.

**Etiology and Symptoms**

The etiology of the arteriolar fibrosis is unknown. Histopathologic findings in the esophagus are the deposition of collagen in the connective tissue and smooth muscle atrophy. These tissue changes result in an aatomic esophagus with a defective or absent lower esophageal sphincter, resulting in significant gastroesophageal reflux often with peptic stricture formation.

**Diagnosis**

The diagnosis of scleroderma is based on physical exam, serum antinuclear antibody levels, and histology. The possibility of esophageal involvement should be suspected in all patients with scleroderma. The involvement of the esophagus is suggested by the symptoms of reflux and dysphagia and confirmed by esophageal motility.

**Videoesophagegram**

A videoesophagegram demonstrates an atomic or “lead pipe” esophagus, often with an associated hiatal hernia.

**Esophageal Manometry**

Esophageal manometry demonstrates ineffective, low-amplitude esophageal contractions involving the distal two-thirds of the esophagus and a defective lower esophageal sphincter manifested by a low sphincter pressure and a short overall and/or abdominal length.

**Treatment**

**Nonsurgical Treatment**

Nonsurgical therapy for the esophageal component of scleroderma includes aggressive acid suppression therapy with proton-pump inhibitors and dilation of esophageal strictures.

**Surgical Treatment**

Esophageal reflux in the setting of scleroderma is difficult to treat surgically. The combination of severe esophageal dysmotility, destroyed lower esophageal sphincter, and delayed gastric emptying leads to gastroesophageal reflux that is also refractory to medical therapy. The two surgical options for such patients are as follows:

1. For patients who do not have a destroyed esophagus, a Roux-en-Y gastric preserving esophageal–jejunal bypass can be done to prevent the reflux of the gastric juice into the esophagus.
2. For patients with a destroyed esophagus from an intractable long stricture or Barrett’s esophagus with high-grade dysphagia, a vagal-sparing esophagectomy can be done.

**SUGGESTED READINGS**

EDITOR’S COMMENTS

When it comes to diseases of the esophagus, there probably is no greater authority than the senior author of this chapter, Tom DeMeester. His contributions to our knowledge of esophageal pathology are legendary, and the DeMeester score for quantitating acid reflux is the standard used worldwide. In this chapter, Banki, a former trainee of DeMeester along with her mentor provide an outstanding summary not just of the various motility disorders but give us detailed step-by-step procedures involved in their operative treatment. This is especially true in their vivid description of the mucosal-stripping vagal-sparing esophagectomy. I must admit that this procedure seems to have some significant advantages to transhiatal esophagectomy when performed for benign disease, and I am surprised that it has not been more widely accepted and utilized.

Perhaps, the most critical issue when dealing with esophageal motility disorders is the decision when to operate or more specifically if an operation is more likely than not to fix a functional problem. When performing nonextirpative surgery the “proof is in the pudding.” That is, if the patient’s symptoms are not improved or alleviated then the patient has undergone an unnecessary procedure. It is clear that certain motility disorders respond better to operation than others and patients should be well informed prior to operation that the result is never “perfect.” For the patient with achalasia, the well-performed myotomy simply allows the esophagus to drain by gravity without obstruction from an incompletely relaxed or hypertensive lower esophageal sphincter but the esophagus obviously remains aperistaltic. I am intrigued by the concept of the peroral endoscopic surgical myotomy and more widespread use of this procedure awaits further outcome data both short-term, specifically morbidity, and long-term functional results.

There is no question that laparoscopic Heller myotomy has, for the most part, replaced the open thoracotomy or thoracosopic approach and has been shown to be highly efficacious in well-selected patients. More recently, robotic Heller myotomy has been used in some centers also with excellent results. The authors favor the routine use of a partial fundoplication as part of definitive treatment for achalasia since most of these patients have some element of acid reflux either preoperative or after the myotomy is performed. I agree with the authors and in experienced hands either the Dor or Toupet partial fundoplication adds little extra time to the operative procedure. The most important aspect of the operation is the completeness of the myotomy being sure to divide every last fiber of circular muscle as well as making sure the length of the myotomy is adequate. Dealing with a failed myotomy presents significantly greater challenges.

LRK
Esophageal Conduits and Palliative Procedures

Jenifer L. Marks and Ara A. Vaporciyan

Esophageal cancer is on the rise throughout the world and esophageal adenocarcinoma is now the most common type of esophageal malignancy requiring surgical resection in the United States. Esophageal resection for benign and malignant cases mandates conduit creation to reestablish gastrointestinal continuity. There are a number of options for conduit creation, including the stomach, colon, jejunum, and a skin tube. Selection depends on a number of patient factors as well as a surgeon’s personal experience with any of the potential conduits. There are advantages and disadvantages for each conduit, and none has proven superiority in all settings. The stomach is the most widely used conduit and therefore has the most data on outcomes. The colon and jejunum are used less often, but are the first choice in some clinical settings such as when the stomach is not available. Skin tube reconstruction has also been described as an esophageal replacement, although utilized uncommonly today. Today’s thoracic surgeon must be familiar with all the conduit choices and understand the technique and implications of using each method for esophageal replacement.

STOMACH

The stomach remains the most commonly used conduit for esophageal reconstruction. It is a large, durable organ with abundant native blood supply and it can be partially or completely tubularized and advanced into the chest or neck for anastomosis to the proximal esophagus. The most important aspect of preparing the stomach as an esophageal conduit is protecting the blood supply for the conduit, the right gastric and right gastroepiploic artery (Fig. 21.1). The remainder of the blood supply to the native stomach is sacrificed during mobilization of the stomach. This includes the short gastric vessels, the pancreaticogastrics, the left gastric artery, and the left gastroepiploic artery. The stomach when used as a conduit is able to survive on the blood supplied by the right gastroepiploic artery because of the stomach’s rich submucosal vascular networks. Radiation can damage these networks and one must always take this into account when operating on patients who have received prior radiation. Alternative conduits should be considered if the stomach does not appear viable after mobilization.

Several aspects of protecting the right gastroepiploic and its vessel of origin, the gastroduodenal artery, deserve mention. When mobilizing the greater curvature of the stomach, care must be taken to palpate the right gastroepiploic artery and stay a safe distance away from it when dividing the gastrocolic omentum with any energy source. Also, the stomach should not be grasped by the greater curvature itself but by the body of the stomach, using gauze or the nasogastric tube to maintain tension. When dissecting the distal greater curvature at the gastrocolic ligament, one must be aware of the gastroduodenal and gastroepiploic artery at all times as this region frequently has redundant folds of omentum making it difficult to identify the artery or the wall of the colon. Careful separation of these folds may be necessary to ensure preservation of the vessel and avoid injury to the colon wall.

The right gastroepiploic artery normally terminates approximately two-thirds of the way along the greater curvature. It is rare for there to be actual continuity in this region of the stomach with the left gastroepiploic or the short gastric vessels but infrequently a collateral arcade may be found within the gastrocolic ligament. This arcade supplies the area distal to the termination of the right gastroepiploic artery and, when preserved, can enhance the blood supply to the distal portion of a conduit. Any major injury or accidental ligation of the gastroduodenal or gastroepiploic artery requires the use of an alternative conduit for esophageal replacement.

The decision to tubularize the gastric conduit is surgeon dependent. Some surgeons prefer not to perform any tubularization, advancing the stomach essentially intact into the chest. While this is an acceptable approach, most surgeons feel that such a conduit leaves the patient more prone to reflux and difficulty with gastric emptying. Therefore, most surgeons advocate some type of tubularization of the stomach.

When performing an intrathoracic anastomosis, the tubularization of the conduit can be done in a number of ways. Some prefer to completely tubularize the stomach while in the abdomen after transection of the distal margin of the specimen. A 4-cm wide conduit is prepared by sequential firings of the GIA stapler with either 4.8 or 3.5 mm loads, depending on the thickness of the organ. The staple line begins at the incisura and ends at the cardia with the proximal extent based on the length of conduit needed and the location of the tumor. The stomach is uncurled and straightened with each successive firing allowing it to lengthen. Oversewing of this staple line with interrupted Lembert stitches for hemostasis as well as to reinforce the staple line may be added. Tubularizing the entire remaining stomach in such a manner provides the greatest possible length allowing the conduit to reach easily into the neck for a cervical anastomosis. For an intrathoracic anastomosis, the proximal end of the now tubularized stomach must be attached temporarily to the distal end of the specimen so that it can be delivered into the chest during the thoracotomy.

An alternate method, when creating a conduit for a thoracic anastomosis, still begins in the abdomen. One or two firings of the stapler are begun at the incisura extending toward to cardia, to begin
The tubularization of the conduit. The stomach is again uncurled as the staplers are applied. The specimen and the conduit remain attached. After the abdomen is closed and the chest is opened, the specimen and conduit are brought through the hiatus. The anastomosis is completed at an appropriate location on the greater curvature of the conduit. The gastric staple line is then completed allowing the specimen to be removed.

Using the stomach for esophageal replacement requires only one anastomosis. As such, it is less technically demanding than any other of the conduit choices. Disadvantages to using the stomach as a conduit include dumping syndrome, early satiety, chronic reflux of gastric contents into the remaining esophageal segment, and the risk of aspiration. Dumping syndrome and early satiety tend to improve with time and lifestyle/dietary modifications. Reflux, regurgitation, and aspiration persist for the remainder of the patient’s life and methods to prevent these sequelae must also be maintained.

Necrosis of the gastric conduit is a rare but very serious and sometimes fatal complication. The most proximal aspect of the conduit is most at risk for ischemia. Early postoperative acidosis or other signs of clinical deterioration should prompt esophagostomy to determine the viability of the conduit. Focal areas of mucosal ischemia can be watched closely as they may progress. An anastomotic leak may also be an early sign of partial conduit necrosis. When gastric necrosis is suspected, the conduit and patient’s status must be monitored closely and the conduit resected if there is any evidence of full thickness necrosis. We do not recommend immediate reconstruction in this situation and a diversion should be performed by stapling off what, if anything, is left of the gastric conduit and constructing a cervical esophagostomy.

**COLON**

The colon is another option for esophageal reconstruction. Either the left or the right colon can be used for conduit creation. Both techniques employ the use of a portion of the transverse colon. Previous abdominal operations or colon pathology may exclude the use of the colon as an esophageal replacement. To assess the suitability of the colon, the surgeon must evaluate its blood supply and the presence of any pre-existing pathology preoperatively. The middle colic vessels provide the blood supply for a right colon conduit, whereas the ascending branch of the left colic provides the supply for a left colon conduit. The transverse colon portion of a left-sided conduit is supplied by the marginal arteries or the arc of Riolan. The colon as a conduit provides more length than is possible with the stomach and can be carried up as high as the pharynx when the blood supply is adequate. Some also believe the colon to be the better choice of conduit for patients with an extended life expectancy since the storage function of the stomach can be preserved. The consequences of an anastomotic leak are often less with a colon conduit since the anastomosis is always placed in the neck. It has also been suggested that over time the colonic conduit is able to generate propulsive forces to help with motility. The colon is resistant to peptic strictures and other late complications seen with a gastric conduit. Finally, the use of the colon maintains the reservoir function of the stomach in those in whom the stomach is not involved with the primary malignancy.

Preoperative evaluation of the colon is required in any patient in which the colon may be utilized as a conduit. Colonoscopy should be performed to rule out any primary colon lesions, significant diverticular disease, or vascular lesions. Alternatively, a double-contrast barium enema may also be obtained. A CT angiogram or MRA should also be obtained to verify the patency of major vessels on which the conduit may be based. A bowel regimen is also recommended preoperatively; a liquid diet for 48 hours prior to surgery is usually sufficient in clearing the colon of large amounts of stool which could hamper the procedure. Oral antibiotics no longer are routinely used as part of the bowel preparation having been supplanted by intravenous antibiotics at the time of surgery.

The procedure is begun by mobilizing either the right or left colon, depending on which is being used. Care should be taken not to injure any vessels in the transverse mesocolon when separating the colon from the omentum. Depending on which colon is to be used, the appropriate feeding vessel is identified via transillumination. The middle colic vessel is used for a right colon graft and the ascending branch of the left colon for a left colon transposition. While the left colon can be utilized as an isoperistaltic conduit, the right colon is positioned in an antiperistaltic orientation. The right colic artery is divided and the conduit is based on the middle colic allowing the proximal colon to be rotated into the neck. After deciding which vessels will be used, the mesentery is opened on the appropriate side of the middle colic vessel. An estimate of the length needed for transposition can be obtained by measuring the distance

**Fig. 21.1.** Blood supply of stomach. (From Fiser SM. The ABSITE Review. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)
from 5 cm below the xiphoid to the angle of the jaw with an umbilical tape. This length is sufficient if the conduit traverses the posterior mediastinum. If the retrosternal route is to be used, the measurement should extend to the earlobe.

Once the length of the graft is determined, temporary vascular isolation is obtained by placing bulldog clamps on the vessels that will be divided. Following this temporary occlusion, it is important to observe the graft for 5 to 10 minutes to assess for any evidence of ischemia or venous congestion. If the graft appears viable, then the appropriate vessels may be ligated. For a left colon graft, the middle colic artery is ligated at its origin from the superior mesenteric artery. For an antiperistaltic right colon graft, the right colic artery is ligated near its origin from the superior mesenteric artery. For an isoperistaltic right colon graft, an uncommon selection because of limitations in length, the middle colic artery is ligated, thus basing the graft on the right colic and advancing the distal end of the colon graft into the neck. Finally, the length of the colon needed is once again confirmed and then the colon is transected 1 cm beyond the remaining marginal vessels. The graft should now be free and ready for transposition.

The graft should be placed retrogastric and can transverse the mediastinum using either a posterior, anterior (retrosternal), or subcutaneous route. Delivery of the conduit through the mediastinum is facilitated using a sterile plastic bag (such as an intraoperative ultrasound bag) into which the conduit is placed for passage. This helps minimize damage to small vessels. When using the retrosternal or the subcutaneous route the hemi-manubrium, adjoining clavicular head and medial first rib on the side of the anastomosis should be removed to provide a more natural lie for the conduit and some additional room. In addition, pressure on the mesocolon or conduit at this location can compromise either the arterial inflow or venous outflow and lead to congestion and potential anastomotic problems. Strictures will also form in this location if there is a constant pressure point on the conduit from the manubrium, clavicle, and first rib.

Advantages to using the colon as a conduit relate mostly to the ability to preserve the stomach. Since the stomach is not a part of the reconstruction, it can be resected for oncologic purposes if necessary such as when dealing with a Siewert type III gastroesophageal junction tumor with extensive involvement of the stomach. In addition, gastric reservoir function of the stomach can be maintained by leaving the native distal stomach in place. This can potentially aid in the resumption of normal dietary habits. Finally, the colon is also a barrier to reflux, providing some protection to the proximal esophagus from bile or acid reflux.

Disadvantages to using the colon relate mostly to the technical aspects related to the procedure. It can be a lengthy operation that requires three anastomoses (esophageal, gastricocolic, and colocolic). Also, up to 30% of patients ultimately will require reoperation after a colon conduit due to redundancy or dilation of the conduit. The development of significant redundancy presents as poor emptying of food into the stomach leading to stasis and dilation within the chest. The optimal time to prevent this complication is at the time of the initial operation by limiting any redundancy of the conduit and performing the cologastric anastomosis high on the posterior wall of the stomach. The length of conduit chosen and its final positioning within the chest must be precise and without excess to avoid a redundant conduit. Any additional length should be placed below the diaphragm and the conduit secured in such a position during the initial operation.

Additional complications associated with the use of the colon include those found with a gastric conduit. These include ischemia or necrosis of the conduit, anastomotic leaks, and stricture formation. Esophageocolonic anastomotic leaks require reoperation for repair less often than an esophagogastric anastomosis perhaps due to the less erosive nature of colonic secretions and its cervical location. Small leaks will often heal without operative intervention. The risk of gastrocolic reflux and peptic colitis can be reduced by placing the cologastric anastomosis high on the posterior portion of the stomach near the greater curvature. Additionally, a short segment of the conduit (8 to 10 cm) is positioned and secured in the infradiaphragmatic position near the hiatus to act as a barrier to reflux from the abdominal to the thoracic portion of the conduit.

**JEJUNUM**

The jejunum that is naturally resistant to both acid and bile offers a third choice for esophageal reconstruction. The abundant length and mesenteric vasculature of the jejunum make it another option for both long and short segment esophageal replacement. The vascular anatomy of the jejunal mesenteric allows the graft to be supercharged using intrathoracic or cervical vessels anastomosed to jejunal vessels. This improves the arterial supply and venous drainage for the graft allowing greater reach.

**Long Segment**

Unlike the colon or the stomach, the existing vascular anatomy of the jejunum limits the length of a graft based solely on any one pedicle. Therefore, the technical aspects of creating a long segment jejunal interposition graft for esophageal replacement are centered around enhancing the collateral blood supply to the segment being transposed into the chest or neck. The proximal jejunum is evaluated and the arcading pattern of its vasculature assessed via translumination (Fig. 21.2A). To use a segment of jejunum, the vascular arcade needs to have several main branches off of the superior mesenteric artery that feed the jejunum in continuous arcades. A segment with three to four sequential branches must be identified. These three to four arcades generally provide a length of up to 50 cm for transposition. The proximal two or three branches are divided while the distal vessel is left intact (Fig. 21.2B). Opening of the mesentery between the arcades may be necessary to straighten the conduit for better function and reach. The distal arcade that is spared functions as the pedicle for the jejunal flap (similar to the left colic arcade for a left colon conduit). Once the segment of jejunum is transposed to the neck, the proximal divided arcade vessel is used for a microvascular anastomosis, providing “supercharging” of the graft. The in situ vessels frequently used for this anastomosis are the internal mammary artery and vein, inferior thyroid vessels, or branches of the thyrocervical trunk. This provides inflow and drainage for the proximal third of the graft. The distal third is supplied by the spared distal arcade vessel, whereas the middle third is supplied by the submucosal collateral vessels from the proximal and distal third (Fig. 21.2C). The retrocolic, retrogastric route is preferred for passage of the conduit and the passage may be either via the posterior, retrosternal, or subcutaneous route.

As mentioned previously as part of the discussion of the colon conduit in the retrosternal position, removing part of the manubrium, the clavicular head, and the medial insertion of the first rib on the side of the esophageojejunosotomy will provide room for the conduit and avoid points of bony compression. Similarly, using a sterile plastic bag to pass the conduit through the mediastinum will protect the thin mesentery and exposed vessels from injury.
Once the graft is positioned in the mediastinum, the microvascular anastomosis is constructed. About 4 to 6 cm of the proximal end of the jejunum is separated from the remainder of the graft while maintaining its attachment to the recently supercharged vascular arcade. This segment of the graft will eventually be exteriorized as an indicator graft to monitor postoperatively the patency of the vascular anastomoses (Fig. 21.2D). The indicator graft is then ligated and excised on the fifth or sixth postoperative day. The esophagojejunal anastomosis is then completed as a single- or double-layer handsewn anastomosis. The nasogastric tube is passed into the mid-conduit under direct vision and palpation to avoid conduit perforation.

Two anastomoses remain for completion of the procedure. The jejunogastric anastomosis is performed on the posterior aspect of the stomach, high on the wall to avoid a saddle bag deformity and poor gastric emptying. The jejunoojejunal anastomosis can be completed in a standard fashion. If the stomach was previously resected, a roux-en-Y jejunoojejunostomy should be performed.

**Short Segment**

A short segment jejunal interposition graft may be used to replace the distal aspect of the esophagus. This procedure has been referred to as the Merendino procedure initially described to correct severe gastroesophageal reflux. Unlike the long segment interposition, a short segment interposition requires mobilization of only one vascular arcade. In addition, this one arcade remains in situ as a pedicle for the graft obviating the need for any additional revascularization. The segment of jejunum is selected on the quality of the vascular arcade as well as its ability to reach the distal end of the transected esophagus. The bowel at the proximal and distal margin of the segment is transected, the mesentery mobilized, and then the segment passed in a retrogastric position. Care is taken to ensure isoperistaltic orientation of the segment. The esophagojejunal anastomosis resides in the chest and is constructed using an ELEA stapler.

**Fig. 21.2.** (A) Transillumination of vascular supply of proximal jejunum. (B) Distal vessels left intact for microvascular anastomosis, the proximal vessels have been ligated. (C) Ischemic proximal third of graft prior to microvascular anastomosis, distal graft perfused by native jejunal vessels. (D) Indicator graft after skin closure.
or can be handsewn if the exposure is adequate. The jejunogastric anastomosis is completed using standard techniques, with care taken to avoid redundancy of the conduit in the upper abdomen. The distal jejunoejunal anastomosis is performed using standard techniques. The mesenteric defect should be closed with care taken not to put any tension on the mesentery of the interposed segment.

Advantages to utilizing a jejunal conduit include the range of lengths that can be obtained and the vascular arcade, which can be easily augmented with cervical vessels and a microvascular anastomosis. The jejunum is perhaps more resistant than the colon to bile and acid reflux that may be present at the jejunogastric anastomosis. The jejunum is a closer size match to the native esophagus than the colon and maintains its peristalsis to help with propulsion of contents through the conduit. That peristalsis can also minimize reflux at the esophageojunal anastomosis as well. Finally, similar to the colon, the lack of reliance on the stomach allows additional stomach to be removed if required for oncologic purposes or preservation of the stomach to maintain its reservoir function.

Disadvantages are all related to the technical aspects of the operation. The reliance on a microvascular anastomosis and submucosal collateral vessels, the duration of the operation, and the additional anastomosis required to reestablish jejunal continuity after creation of the conduit all can lead to potential complications. Additionally, obesity can lead to shortened fatty mesenteries that limit the reach of the jejunum and greatly increase the technical complexity of the operation.

**SKIN TUBE**

In some situations, when none of the commonly utilized conduits are available for reconstruction, a skin tube may be constructed and used as an esophageal conduit. The procedure has been described in the literature and can provide acceptable results when there are no other options for reestablishing gastrointestinal continuity. The basic technique employs a myocutaneous flap that is rolled into a tube with the skin oriented internally. Myocutaneous flaps have been based on the latissimus dorsi, trapezius, and deltoid/pectoralis muscles. A free flap from the anterolateral thigh has also been described. Methods for creating the conduit vary based on the donor site but technically a skin tube is created first. The position of the tube is always subcutaneous. Once its viability is established the proximal and distal anastomoses to the esophagus and stomach or jejunum (if no stomach remains) are constructed.

This conduit is always a conduit of last resort and as such is used only in the most extreme circumstances. When compared with other conduits, it has no natural advantages other than its availability when all other conduits have been exhausted. Its disadvantages clearly derive from its many technical complexities but are also secondary to the existing comorbidities of the patient.

**CONDUIT POSITION**

For an intrathoracic esophageal anastomosis, the posterior mediastinal route is the only option. However, when the conduit must reach the cervical esophagus three distinct routes are available: the posterior mediastinal, the anterior mediastinal (also referred to as the retrosternal), and subcutaneous route. In general, if the posterior mediastinum is available, this is preferred as it provides the most natural position and shortest route for any esophageal conduit. An exception to this can exist when a long segment jejunal or a supercharged colon conduit is utilized since exposure and construction of the microvascular anastomoses can be easier after retrosternal positioning and resection of the manubrium. If previous resections or disease in the posterior mediastinum have created a hostile environment, the anterior mediastinum (retrosternal) is the next choice. This still provides the conduit with bony protection and is generally an easy plane to develop in the absence of a prior sternotomy. As mentioned previously, this route should be accompanied by the removal of a portion of the manubrium, the clavicular head, and the medial insertion of the first rib on the side of the esophagoconduit anastomosis to avoid compression of the conduit at the thoracic inlet. Dysphagia is more common with a retrosternal conduit due to angulation as food passes from the posterior mediastinum, the native location of the proximal esophagus, to the anterior mediastinum, where the new conduit is positioned. This angle and subsequent dysphagia can persist despite removal of the clavicular head and hemi-manubrium. However, failure to remove the bony segments can increase its frequency and also lead to compression of the conduit and eventual stenosis.

The subcutaneous route is most frequently used when the posterior and anterior mediastinum are unavailable. While the subcutaneous route can still provide adequate resumption of enteral intake, the conduit is frequently visible, especially during oral intake and can be unsightly. In addition, the angulation from the posterior mediastinum for the cervical esophagus to the subcutaneous position of the conduit is at its most extreme. This can lead to an even greater degree of dysphagia than seen with the anterior mediastinal route. Finally, the length of conduit required is the greatest when using this route and care must be taken to ensure that adequate conduit length is available.

**PALLIATIVE PROCEDURES**

Fifty to sixty percent of patients with esophageal cancer will present with unresectable locally advanced or metastatic disease. In addition, other patients may have technically resectable disease but their diminished performance status or coexisting comorbidities preclude surgical resection. While many of these patients without metastatic disease may be offered curative chemoradiotherapy, many may eventually be referred for palliation of disabling symptoms. Pain, dysphagia, bleeding, perforation, and fistula formation are the most common symptoms requiring palliation. The palliative techniques available broadly can be grouped into endoscopic, radiation, and surgical techniques.

Of all the symptoms that may need to be addressed dysphagia is the dominant one. Palliative radiotherapy or chemoradiotherapy provides relief of dysphagia in the majority of patients presenting with advanced disease. The necessity of additional procedures will depend on individual patient responses, the severity of symptoms that remain, and the life expectancy of the patient. Bleeding, perforation, and fistulas are the next most commonly addressed sequelae that require intervention. Pain is largely addressed with medication and usually does not require invasive procedures for palliation. An exception to this is pain secondary to direct invasion of the spine, which can sometimes be addressed with external beam radiation.

**Endoscopic Palliative Procedures**

There are a number of endoscopic means of providing palliation for patients with advanced esophageal cancer. Dysphagia is the most common symptom requiring endoscopic therapy for palliation. Sometimes, others problems such as bleeding, perforation, and fistulas can also be addressed endoscopically. The treatment modalities range from simple mechanical
or balloon dilation with or without stent placement, and ablative therapies. Often these modalities are used in combination with one another or with systemic chemotherapy or radiotherapy to provide the most durable palliation possible.

**Dilatation**

Simple mechanical dilatation of an esophageal stricture or localized site of disease is an effective means of relieving dysphagia. Savory dilators or balloon dilation can be used in attempts to achieve a patent lumen. Dilatation should be performed under guidance, either directly via the endoscope or fluoroscopically. Blind Maloney dilatation in diseased tissues increases the risk of perforation and is not recommended. Repeat dilatation is almost always necessary as dilatation without a stent is usually of limited durability. Dilatation is often necessary as an initial step in endoscopic therapy to achieve a lumen of adequate size for the application of other treatments, such as stent placement and ablative therapies.

**Stents**

The most common indication for an esophageal stent is following a dilation procedure when it is used to maintain the patency of the strictured or obstructed esophagus that has been opened. Perforation and fistula formation are other common indications where the stent can limit the contamination that can result. When deployed for dysphagia, stents can be used to treat both endoluminal obstruction as well as external compression caused by mediastinal involvement. Stents should be sized so that there is at least 2 cm of length on either side of the stricture allowing the proximal and distal ends of the stent to anchor in normal tissue. This can be difficult for distal or very proximal lesions. For distal esophageal strictures, the proximal portion of the stent should be at least 2 cm above the stricture to anchor the stent. The distal portion of the stent will be free within the stomach. Stenting across the GE junction in this fashion will lead to wide open reflux and regurgitation. This must be discussed with the patient prior to stenting as these symptoms may be as troublesome as the dysphagia. Proximal lesions can be even more difficult to address with a stent. If the stent must lie at or near the cricopharyngeus patients may experience a continuous persistent globus sensation, which can limit patient tolerance. In addition, the limited length of uninvolved esophagus proximal to the obstruction prevents an adequate landing zone making stent migration a common problem.

There are a number of stents available for use. Familiarity with each stent, their delivery system, and their available lengths and widths prior to performing the procedure is vital. Two major varieties of stents exist: the self-expanding metal systems and plastic systems. Self-expanding metal stents (SEMS) are composed of a variety of metal alloys and are available either covered or uncovered. Other features that must be selected include the length and width as well as whether the stent will be deployed from the distal end or the proximal end of the delivery system. Both covered and uncovered versions provide almost immediate relief of dysphagia but each can also cause some degree of discomfort due to their radial force. Most of the SEMS available in the United States are made of nitinol and are better tolerated than stainless steel stents secondary to their gradual expansion, although they may not provide the same rapid relief of dysphagia. Concomitant mechanical dilatation after deploying the stent can speed relief of the dysphagia. The covered stents provide a barrier to tissue in-growth and also address contamination in cases of perforation or a fistula. Alternatively, solid plastic stents are also available and are designed for easier removal. The delivery systems utilized by these types of stents tend to be bulkier but they also provide rapid relief of dysphagia.

Stent removal may sometimes be necessary if patient discomfort is excessive or if stent migration occurs. The initial SEMS were not meant to be retrievable and can fracture if removal is attempted, especially after significant tissue or tumor in-growth. The more recent versions of SEMS and the plastic stents come with a loop of suture on the proximal end that is meant to be grabbed and use to collapse and remove the stent.

Stent migration is a problem with all devices. Displacement most commonly occurs secondary to normal esophageal motility. Alternatively, if the stent is positioned low on the tumor, it can propel the stent distally as it grows. It occurs more commonly with covered or plastic stents, as these resist incorporation by tissue or tumor in-growth. Regardless of which type of stent is used, all stents should be monitored periodically for migration.

When attempting to cover a perforation or fistula, a covered stent is necessary. After stent placement, all patients should be evaluated with a contrast study to confirm complete exclusion of the defect. Complete exclusion may not be necessary if a perforation can be diminished significantly, intrathoracic drainage is adequate, and the patient’s life expectancy is limited. However, if complete exclusion must be obtained then a second stent may be needed. Even after complete exclusion is obtained, the patient should continue to be monitored as displacement of the stent can lead to a recurrence of the defect. Proximal defects are especially difficult to control and bridling of the stent around the nasal septum is one way to try and prevent stent migration (Fig. 21.3). One end of an umbilical

---

*[Fig. 21.3. Bridling of the esophageal stent to prevent migration. (Courtesy of Shanda Blackmon.)*]
tape is passed through the nostril and out the mouth, then through the stent and the stent is positioned. The other end of the umbilical tape is then brought out the other nostril and the ends secured at the nasal septum. This can prevent distal migration of the stent but still must be monitored to prevent pressure necrosis on the patient’s nasal septum from the umbilical tape.

The technique of placing kissing stents, two stents in neighboring organs/vessels, can be used for fistulas between the esophagus and the trachea or rarely the esophagus and the aorta. Endovascular stenting of the thoracic aorta to treat an esophagogastric fistula has been described and can provide a temporary solution to a life-threatening problem. For a malignant fistula in this setting, we generally do not recommend aggressive surgical intervention due to the overall poor prognosis. When treating a tracheoesophageal fistula with kissing stents, the esophagus should be stented first, followed by the trachea. This helps to limit contamination of the airway and sometimes the esophageal stent is all that is necessary to control the fistula. As always with any esophageal perforation, a collection within the chest or mediastinum should be drained with open or interventional drainage.

Ablative Therapies

Photodynamic therapy (PDT) and laser ablation are both commonly used to palliate symptoms of advanced esophageal cancer. Ablative therapies can provide rapid palliation of both bleeding and dysphagia and are generally well tolerated by most patients. Proximal and distal/GE junction tumors are best treated with this modality due to the issues with stenting. The proximity of the airway to mid-esophageal lesions can make this area prone to complications when ablative therapy is used here.

Photodynamic Therapy

PDT is performed by first administering a photosensitizing agent intravenously. Two days following the injection the region of the involved esophagus is exposed to a low power activating laser light delivered through the endoscope. It is believed that malignant cells take up the photosensitizing agent at a higher concentration than normal cells. This makes them more sensitive to the effects of the sensitizing agent after exposure to the activating wave length of light. Upon exposure to the 630 nm wavelength laser, the sensitizing agent is converted to a toxin with direct effects mediated via oxygen free radicals. Tumor cells along with their microvasculature are destroyed and the tumor becomes ischemic. Repeat endoscopy is performed 2 days after laser exposure, necrotic tumor debried, and another exposure to the laser can be performed at this time. The amount of total light exposure determines the degree of tumor necrosis.

Increased tumor necrosis with more light exposure must be balanced against the risk of perforation, which occurs in approximately 2% of patients. Side effects such as chest pain, odynophagia, and pleural effusion occur frequently. Development of a tracheoesophageal fistula is a much more serious event that is reported in 5% to 30% of patients. This occurs more often when the mid esophagus is being treated due to its proximity in the airway. Esophageal stricture is also reported in up to 10% of patients after PDT. Patients must also be instructed to avoid prolonged exposure to sunlight and bright indoor lights after receiving the photosensitizing agent as extensive skin burns have been described due to cutaneous photosensitivity. Mild skin irritation often results from even incidental light exposure. It is recommended that patients remain completely protected from sunlight and bright indoor light in addition to eye protection from their initial injection and for at least 4 to 6 weeks after the injection. Sun block is not effective in preventing this type of burn. These restrictions must be fully discussed with the patient prior to planning their injection. After an initial PDT treatment, patients may experience tumor regrowth within 2 to 3 months and may require further therapy. PDT may be repeated or used in combination with other treatments.

Laser Ablation

Direct thermal ablation of esophageal lesions for palliation has been traditionally performed with the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. This laser is easily applied using a fiberoptic delivery catheter placed through the endoscope. The depth of penetration may be limited and associated with minimal collateral damage by carrying out precise ablation of malignant tissue. Concurrent mechanical debridement with rigid endoscopic forceps can hasten tumor removal especially when dealing with large bulky tumors. Most patients will require several treatments and even then the duration of relief provided is limited usually to 1 to 2 months. Laser therapy can be combined with other modalities for a more durable response. For example, the Nd:YAG laser can be used initially to open a severe stricture or total obstruction followed by stent placement.

Serious complications include perforation (8%), tracheoesophageal fistula (6%), and death (5%). Fire is also possible if high concentrations of oxygen are used in close proximity to the laser. This should always be kept in mind when using a laser near the airway.

External Radiation and Brachytherapy

Many patients with unresectable locally advanced esophageal cancer will receive external beam radiation therapy as part of their initial treatment. External radiation in combination with chemotherapy is associated with response rates as high as 80% achieving significant symptom relief with perhaps one-third of those patients achieving a complete response. Unfortunately, despite the initial response, up to half of these patients will recur locally and may eventually need palliation. For these patients, radiation therapy options for palliation are limited and alternative options described above will need to be considered. For those patients who require palliation and who did not previously receive radiation therapy, external beam radiation should be considered and is generally well tolerated.

Endoluminal brachytherapy is another option for local treatment of lesions causing symptoms and may be an option even in those patients who previously received external beam radiation. Both low- and high-dose endoluminal regimens are available with the low-dose regimens being better tolerated but taking a longer time to achieve symptom palliation. High-dose rate brachytherapy (HDR-ILRT) consists of 12 to 20 Gy given in one or two fractions and is the preferred method of delivery due to high success rates and the rapidity of symptom improvement. Esophageal stricture and fistula formation are potential complications of brachytherapy. The incidence of fistula formation ranges from 0% to 12%, while strictures are more common and can range from 10% to 35%.

Surgical Palliation

Open surgical procedures as palliation for esophageal cancer should be considered only after other less invasive means have failed. Symptoms such as bleeding, dysphagia, perforation, and fistulas have all been addressed surgically. Dysphagia and minimal bleeding are unlikely to require surgical intervention as these symptoms often respond to chemotherapy and radiation or endoscopic treatment. Life-threatening
bleeding due to erosion into a major vessel can be treated surgically if endoscopic techniques are unsuccessful. However, before such heroic actions are attempted, a frank conversation with the patient and their family members must take place regarding the overall prognosis. These palliative procedures are associated with significant morbidity, and if the estimated life expectancy is shorter than the time required to recover from the operation, there may not be any meaningful palliation achieved.

Operative repair often entails vessel ligation (if the vessel is not the aorta), debridement and closure of the esophagus, if possible, and soft tissue coverage of the fistula. Alternatively, a stent may be used to control the esophageal defect while the vessel is ligated surgically. An esophagoaortic fistula presenting with massive hemoptysis can be treated with both esophageal and endovascular stents; however, the overall prognosis needs to be weighed heavily against such heroic palliative interventions.

When faced with severe dysphagia, there are rare scenarios where the disease does not respond to medical or endoscopic therapy. In these cases, surgical bypass may be the only option for palliation or obstruction. Retrosternal gastric bypass can be performed with the intent of allowing the patient to recover the ability to eat. Unfortunately, such procedures have morbidity rates of up to 60% and mortality rates of 5% to 10%. They require long recovery times and may not actually improve the patients’ quality of life depending on the postoperative course. Lifestyle modifications necessary after undergoing such a procedure, and the natural history of their advanced disease.

Another form of surgical palliation for severe dysphagia is in the provision of enteral access. Either a jejunostomy or gastrostomy can be performed in patients with esophageal cancer. The timing of placement depends on each individual patient’s disease course, their wishes, and tolerance of treatment. Some patients need feeding access upon presentation due to weight loss and disease-related malnutrition, others require it during induction therapy due to ongoing dysphagia, odynophagia, or oral intolerance, surgical candidates usually have one placed during the resection, and finally some patients have it placed toward the end of their disease course as they lose the ability to sustain themselves with oral intake alone. Regardless of when it is placed, laparoscopic, open, or endoscopic methods can be used and are well tolerated. Jejunostomy tube placement is preferred over a gastrostomy if the patient possibly is a surgical candidate due to concerns of compromising the gastroepiploic artery with gastrostomy tube placement.

When perforation of the esophagus occurs in a patient with incurable esophageal cancer, the role of surgical palliation must be carefully considered. The perforation may be primary from the tumor itself or secondary and related to endoscopic interventions. While most can be approached with placement of a stent, some are not amenable to such an approach or stent bypass may fail to achieve isolation of the leak. The first decision to be made in these cases relates to the patient’s performance status and life expectancy. Patients with otherwise treatable disease should be treated aggressively with the hope of being able to complete the treatment regimen and prolong life. However, patients with limited life expectancy whose symptoms can be managed without surgical intervention should not be subjected to heroic options where only limited palliation can be achieved. In these cases, a stent sometimes accompanied by a mediastinal or intrathoracic drain can control the mediastinal spillage and avert sepsis in most situations at least temporarily. If the stent is not effective at preventing sepsis and the patient is not likely to succumb to his disease within 4 to 6 weeks, one can consider proximal diversion. It should be considered as a last choice for control of sepsis only. The overall prognosis should be considered when dealing with these difficult situations. Resection should not be considered in patients with uncontrollable local and metastatic disease.

Malignant tracheoesophageal fistula formation is another clinical situation in which some form of palliation may be indicated. This problem is largely addressed endoscopically with esophageal and/or tracheal stent placement to control pulmonary sepsis and ongoing aspiration. These patients generally present in poor condition and palliation via the least invasive means possible is the best option. Primary tracheal repair with muscle coverage and proximal diversion or resection can be considered in some rare situations.

A posttreatment fistula with no evidence of disease, for example, a high squamous cell carcinoma with a complete clinical response to therapy and delayed fistula formation, might warrant consideration of surgical intervention if the patient is in good medical condition.

CONCLUSION

The modern esophageal surgeon has multiple options available for both reconstruction of the esophagus and palliation of symptoms. Blind adherence to one method is no longer an option as there clearly are clinical scenarios where alternative approaches may be beneficial to the patient. Even if one is not competent at performing each of the various options, a treating physician should at least possess an understanding of the available options and use that knowledge to guide the patient to the best treatment.

SUGGESTED READINGS

SUGGESTED READINGS

As the authors point out gastric transposition, far and away, is the first choice for reconstitution of the gastrointestinal tract following esophageal resection. If for whatever reason the stomach is not available to use as a conduit, the colon remains the next best choice but introduces an additional level of complexity, in that it requires three anastomoses and is accompanied by a higher incidence of complications. A long segment jejunal graft introduces even more complexities, in that supercharging with a microvascular anastomosis is usually required.

Mobilizing the stomach for use as a conduit requires careful preservation of the right gastroepiploic artery. If a patient has had previous upper abdominal surgery, confirmation of a patent gastroduodenal artery and right gastroepiploic artery should be carried out prior to esophagectomy. Preparation of the gastric conduit should involve some level of tubularization of the stomach both to achieve adequate length and also to facilitate gastric emptying. In addition an emptying procedure, either pyloromyotomy or pyloroplasty should be performed. Ideally, the conduit should reside in the posterior mediastinum as it provides the shortest route to the neck, assuming the anastomosis is to be done in the neck.

The keys to a successful anastomosis include no tension and an adequate blood supply. Care should be taken in handling the gastric remnant to avoid submucosal hemorrhage. As mentioned, if the gastric conduit or colon is brought up via the substernal approach, the ipsilateral hemi-manubrium and clavicular head should be removed in order to prevent compression of the conduit. Anastomotic leaks in the neck usually can be managed simply by opening the skin to allow drainage. An intrathoracic leak may be more devastating but usually may be managed conservatively as long as there is adequate drainage.

Palliation of esophageal carcinoma raises a number of issues. As the authors point out, there are a number of options for palliation of the major symptoms with the dysphagia being the most frequent indication for palliation in those patients who are either inoperable or unresectable. Careful consideration should be given prior to subjecting a patient a palliative procedure taking into account the predicted length of survival. The occasional patient may be a candidate for the ultimate palliative procedure, substernal gastric bypass, but as the authors point out this procedure is associated with significant morbidity. For the rare patient, who presents fairly early with a tracheoesophageal fistula but has remained in reasonable shape, substernal gastric bypass may be the procedure of choice to allow both for bypass of the fistula and protection of the lungs in addition to allowing the patient to resume oral alimentation.
Diverticula of the esophagus are uncommon disorders that are usually classified according to their location (cervical, thoracic, or epiphrenic), their pathogenesis (pulsion or traction), and their morphology (true or false).

The great majority of esophageal diverticula are acquired lesions that occur predominantly in elderly adults. Pulsion, or false, diverticula are the most commonly encountered type of esophageal diverticula. These localized outpouchings lack a muscular coat, and their wall is formed entirely by mucosa and submucosa. Almost all are the result of a functional obstruction to the advancing peristaltic wave, usually caused by an abnormal upper or lower esophageal sphincter. Occasionally, impedance to peristaltic progression may be the result of peptic strictures or localized motility disorders such as spasms. Pulsion diverticula thus occur most commonly at the level of the cricopharyngeus where there is a weak area of the crossing muscle fibers in Killian’s triangle or the distal 10 cm of the thoracic esophagus between the inferior pulmonary vein and the diaphragm (epiphrenic location); however, they may also occur within the midthoracic esophagus.

True, or traction, diverticula are usually seen in the middle one-third of the thoracic esophagus in a peribronchial location. These diverticula are the result of para-esophageal granulomatous mediastinal lymphadenitis secondary to disorders such as tuberculosis or histoplasmosis. The ensuing desmoplastic reaction tents the full thickness of the esophageal wall, producing a conical, wide-mouthed true diverticulum. They most frequently project to the right because subcarinal lymph nodes in this area are closely associated with the right anterior wall of the esophagus. These outpouchings are rarely seen in the Western world and are usually of little or no clinical significance except in rare instances when ongoing mediastinal inflammation results in a fistulous communication with the airway or other intrathoracic structures.

ZENKER’S DIVERTICULUM

The British surgeon Abraham Ludlow is credited with the original description of a pharyngoesophageal diverticulum from an autopsy specimen that remains on display at the Royal Infirmary Pathology Museum in Glasgow, Scotland. Almost a century later, the German pathologist Zenker provided a complete clinical and pathologic description of 34 cases. The pathogenesis of this lesion was first suggested in 1926 by Jackson, who proposed that the tonically contracting upper esophageal sphincter (UES) impeded the progress of the swallowed bolus. A localized increase in intraluminal pressure forces the mucosa to herniate through the posterior midline of the inferior pharyngeal constrictor in the anatomically bare area (Killian’s triangle) between the oblique fibers of the thyropharyngeus and the horizontal fibers of the cricopharyngeus. The diverticulum deviates away from the rigid vertebrae and usually presents on the left side. The exact nature of this cricopharyngeal motor dysfunction remains unclear, but most commonly an incomplete or incoordinated opening of the UES is present.

CLINICAL PRESENTATION

Zenker’s diverticulum is primarily a condition of the elderly and is twice as common in men. Dysphagia for solid food and regurgitation of undigested food are the most common symptoms and are typically present. Halitosis, noisy swallowing or “gurgling” after deglutition, and globus sensation are also common. Aspiration may also result from this condition, and it may manifest as a mild nocturnal cough, morning hoarseness, or new onset adult bronchospasm caused by repeated laryngeal penetration and irritation and, on rare occasion, present as chronic lower respiratory tract infection or even lung abscess. Despite the association among hiatal hernia, gastroesophageal reflux, and Zenker’s diverticulum, only a few patients present with severe heartburn and rarely do they require surgical correction of their reflux.

DIAGNOSIS

A barium esophagogram using a lateral or oblique projection usually demonstrates the diverticulum, which can be large and may protrude well into the superior mediastinum (Fig. 22.1). Esophageal manometry adds little information and should not be routinely performed. Endoscopy can be considered but often adds little to the diagnosis. Perforation of the diverticulum can result from aggressive endoscopic examination because the flexible endoscope often enters the diverticulum rather than the true esophageal lumen. Malignant change is possible but is exceedingly rare in these diverticula, with squamous cell carcinoma having been reported in no more than 0.5% of patients. If diverticulopexy is planned, the diverticulum should be carefully palpated to rule out a nodular density in the wall, and an intraoperative endoscopic examination can be performed to evaluate the interior of the sac as there will be no pathologic specimen.

TREATMENT

A small, completely asymptomatic diverticulum in an elderly patient with comorbidities that preclude general anesthesia likely can be safely observed. However, in most patients, once a diagnosis is made, treatment is suggested because these diverticula will often enlarge over time and can lead to the more bothersome complications such as aspiration. The gold standard for the surgical treatment of Zenker’s diverticulum is cricopharyngeal myotomy combined with either diverticulectomy or diverticulopexy via an open transcervical approach. However, advances in instrumentation for minimally invasive surgery now allow for...
the management of Zenker’s diverticula via transoral endoscopic creation of a stapled esophagodiverticulostomy in many patients. This procedure utilizes a rigid diverticuloscope and an endoscopic GIA stapler to create a cricopharyngeal myotomy while bringing together the lumina of the pouch and esophagus. We believe that carefully selected patients may be offered endoscopic management with the caveat that conversion to an open procedure may be necessary should the minimally invasive approach prove technically unfeasible intraoperatively.

Endotherapy utilizing flexible endoscopes and various energy sources to divide the septum between the diverticulum and esophagus (which contains the cricopharyngeus muscle) has become more commonplace. These procedures are typically performed in an endoscopic unit by gastroenterologists. The purported benefits of this approach include the ability to perform the procedure without general anesthesia or neck extension. As only a 1.5- to 2-cm incision in the septum is recommended by most authors, diverticula >3 cm require longer incisions and, therefore, repeat procedures. A recent review of these procedures reports mediastinal emphysema from presumed microperforation in over 20% of patients and a clinical recurrence rate of approximately 20%. Given the exceptional results and minimal morbidity associated with both the traditional open repair and the transoral stapled procedure, we feel that these flexible endoscopic techniques should be reserved exclusively for poor operative candidates.

**PREOPERATIVE MANAGEMENT**

Endoscopic management may not be the preferred procedure in some patients due to anatomic constraints. Difficulty may be encountered in placing the diverticuloscope in patients with retrognathia, limited jaw mobility, prominent incisors, or rigid cervical kyphosis that limits neck extension. In a prospective study of factors predicting endoscopic exposure and repair of Zenker’s diverticulum, the endoscopic procedure was unsuccessful in 30% of patients. Patients with short necks, high body mass index (BMI), and decreased hyomental distance were less likely to have successful endoscopic repair, and the authors advocate an open approach in such patients. In addition, the size of the diverticulum on barium esophagogram should be assessed because small diverticula (<3 cm) are generally not amenable to stapling. A small pouch limits access of the stapler anvil and prohibits the attainment of an adequate length of myotomy. Diverticula >6 cm should also be managed with an open approach because endoscopic stapling results in a large pharyngeal cavity that does not empty completely. This information is helpful in preoperative discussions with the patient concerning the likelihood of conversion to an open procedure. All patients should be prepared and give consent for an open procedure in the event that endoscopic instrumentation proves unfeasible or a complication is encountered. Patients are instructed to limit their diet to clear liquids the day before surgery.

Although many cervical operative procedures may be performed under local anesthesia, general endotracheal anesthetic is suggested for this procedure, along with the usual preincision antibiotic prophylaxis.

**ENDOSCOPIC SURGICAL TECHNIQUE**

After induction of general anesthesia, a shoulder roll is placed to achieve neck extension in the standard position for rigid esophagoscopy. An upper jaw dental guard is placed. Direct endoscopy is performed using a lighted suspension laryngoscope. The esophageal lumen, diverticular lumen, and their common wall are visualized. The distal blades are opened slightly to enter the esophagus anteriorly and the diverticular lumen posteriorly. The distal blades of the instrument are opened, keeping the common wall between the esophagus and diverticulum centered in the scope’s aperture. The proximal scope is then widened, and the laryngoscope is attached to a suspension system to allow for bimanual instrumentation during the stapling procedure. A 0-degree bronchoscopic telescope attached to an endoscopic camera is then inserted laterally through the laryngoscope. The pouch is examined to exclude malignancy and to assess the depth of the pouch and length of the septum. A 30-mm linear GIA stapler is then introduced through the laryngoscope, and its jaws are positioned on the common wall with the longer end containing the staple cartilage within the esophageal lumen. The position of the jaws is confirmed using the telescope. If the position of the jaws is in question, the stapler is opened and the device reapplied. If necessary, traction sutures can be placed laterally in the common wall using an endosuture device and used to help pull the common wall into the jaws of the stapler. If proper positioning of the stapler cannot be confirmed before firing,
the minimally invasive approach cannot safely be performed and should be abandoned in favor of an open procedure. Once proper position is confirmed, the stapler is fired and removed. The stapler divides the common wall, including the cricopharyngeus muscle, between the diverticulum and esophagus and closes the wound edges with a triple row of staples on each side. The divided edges of the septum should retract laterally revealing an open esophageal lumen. The cut edges should be inspected to ensure hemostasis. Should a significant septum and diverticular sac still be present, a second stapler application should be performed in a similar manner. Once the septum is completely divided and hemostasis is confirmed, the procedure is terminated. Patients are offered a liquid diet the following day, and if fluids are tolerated, they are advanced to a soft diet and discharged on the second postoperative day. All patients should have a chest radiograph postoperatively to exclude perforation, which more than likely would manifest as air in the retropharyngeal space or mediastinum.

**OPEN SURGICAL TECHNIQUE**

After general anesthesia is induced, a shoulder roll is placed and the neck is extended with the head turned slightly to the right. An incision with its midpoint based on the cricoid cartilage is made along the anterior border of the left sternocleidomastoid muscle down. The subcutaneous tissue and platysma are subsequently divided. A superficial cervical cutaneous nerve is present in the upper one-third of the field and should be protected if possible to prevent postoperative dysesthesia of the submandibular skin. The incision is deepened through the cervical fascia medial to the sternocleidomastoid muscle. The fascia overlying the omohyoid muscle is incised, and the muscle is divided. The prethyroid muscles are retracted medially to reveal the thyroid gland, the jugular vein, and the carotid artery. The middle thyroid vein is ligated and divided, and the larynx is retracted medially. The inferior thyroid artery is ligated and divided as laterally as possible to protect the recurrent laryngeal nerve, which is located immediately beneath its branches in the tracheoesophageal groove behind the thyroid. The thyroid and cricoid cartilage are rotated medially while retracting the carotid sheath and its contents laterally. Manual retraction of the larynx with an assistant’s finger is preferred to self-retaining devices or hand-held metal retractors to prevent a traction or direct compression injury to the recurrent laryngeal nerve. With the use of blunt dissection, the prevertebral fascial plane is entered posterior to the esophagus and diverticulum, and further rotation of the larynx then everts the lateral posterior pharyngoesophageal junction. The diverticulum can usually be visualized adherent within its filmy attachments to the posterior aspect of the cervical esophagus at or below the level of the cricoid cartilage. The adventitial tissues are gently dissected in the posterior midline to free up the pouch. The tip of the diverticulum is grasped with an atraumatic Babcock or similar type of clamp and is dissected away from the esophagus using a combination of sharp and blunt dissection (Fig. 22.2). The sac is elevated until its neck is clearly defined, and this may require some additional sharp dissection from the known surface of the diverticular sac toward the investing muscle fibers and scar tissue, if present. Once the neck of the diverticulum is displayed, a cricopharyngeal myotomy is created starting at the inferior border of the diverticulum on the left posterolateral or posterior aspect of the esophagus. The muscle is separated from the underlying submucosa bluntly using a small rightangled clamp. The myotomy should be extended inferiorly for approximately 3 cm (Fig. 22.3). The mucosa will bulge between

---

the edges of the sectioned muscle. With the myotomy completed, small diverticula (<1 cm) will often disappear when released into the bulging submucosa, and thus myotomy alone is sufficient. Those that do not spontaneeusly resolve should be further treated with either diverticulopexy or excision. Diverticula <5 cm in length are amenable to diverticulopexy, which is a simpler and faster procedure that does not require opening of the esophageal lumen. Following the myotomy, the tip of the diverticulum may be suspended either to the posterior wall of the pharynx or to the prevertebral fascia with two to four simple 3-0 silk sutures (Fig. 22.4). Care should be taken not to transfix the sac to avoid any contamination of the surgical field. Diverticula >5 cm are too large to be suspended and should usually be resected. After myotomy, a large bougie (40F or larger, depending on patient size) is inserted into the cervical esophagus to prevent excessive mucosal resection which could narrow the esophageal lumen. If possible, a linear stapling device is applied transversely across the neck of the sac, and the sac is transected distal to the staple line. In the rare cases in which a stapler cannot be applied, the sac may be resected and the defect repaired using interrupted sutures. Care must be taken here not to remove an excessive amount of mucosa with the resection. It is better to have more than needed because tissue can be gathered into the suture line to make the lumen attain an appropriate size. Before closure, a nasogastric tube is passed into the proximal esophagus, and the mucosal integrity is tested by air insufflation by placing saline in the incision and compressing the distal esophagus below the nasogastric tube. The nasogastric tube is subsequently removed, and after hemostasis is ensured, the wound is closed in two layers without drainage. If the ends of the omohyoid are large enough, they may be reapproximated using a figure-of-eight suture technique. Patients are allowed a clear liquid diet the morning after surgery and advanced to a soft diet the following day in most cases. Most patients are discharged on the second or third postoperative day. A postoperative barium swallow is not routinely obtained before discharge. Patients should maintain a soft diet for the first week following surgery.

**SURGICAL RESULTS**

There have been no prospectively randomized, controlled trials comparing the different open surgical approaches, nor
have there been randomized studies comparing endoscopic stapled esophagodiverticulostomy with open surgical techniques. Series of stapled esophagodiverticulostomy have reported satisfactory outcomes in approximately 90% of patients undergoing successful endoscopic repair, with both morbidity and recurrence rates <10%. These figures closely approximate those reported in series of open surgical techniques. Complications are similar after both techniques and most commonly include hemorrhage, transient vocal cord paralysis, and perforation resulting in mediastinitis. In a large retrospective Italian series of 297 patients who underwent either transoral stapled esophagodiverticulostomy or open cricopharyngeal myotomy and stapled diverticulectomy, >90% of patients were symptom-free or significantly improved after a median follow-up of >2 years regardless of the approach. Patients who underwent transoral stapling for a diverticula <3 cm were more likely to have persistent dysphagia, presumably because the common wall was too short to allow complete myotomy. Advantages of the minimally invasive approach included shorter anesthetic time, earlier resumption of normal diet, and shorter hospital stay. The endoscopic stapling technique is an effective procedure in patients with medium-sized diverticula (3 to 6 cm). However, certain patient characteristics have been demonstrated to limit successful endoscopic exposure and repair. In our opinion, conventional open repair techniques are very well tolerated and remain the gold standard therapy at present.

**THORACIC DIVERTICULA**

Diverticula of the thoracic esophagus are relatively uncommon and typically account for <30% of all esophageal diverticula. As stated earlier, their classification according to location or pathogenesis is probably unnecessary because midesophageal traction diverticula are now a rarity in the Western hemisphere. Almost all thoracic esophageal diverticula are associated with and perhaps caused by an esophageal motor disorder, most commonly achalasia, diffuse esophageal spasm, hypertensive lower esophageal sphincter, and nonspecific motor disorders. Using cinefluorography and manometry, Cross et al. concluded that in 150 patients with esophageal disorders, esophageal diverticula were the result of excessive intraluminal pressures. This segmental increase in pressure, caused by increased esophageal tone or a delay in sphincteric opening, acts on weakened areas of the esophagus and results in outpouching of the mucosa.

**CLINICAL PRESENTATION**

Most patients are older than 60 years of age, and many are asymptomatic or have only minimal and often vague symptoms. There is usually no correlation between diverticular size and the presence of symptoms. Many vague symptoms may be attributable to the underlying motility disorder rather than the diverticulum. Symptoms include dysphagia, postural regurgitation, belching, retrosternal pain, heartburn, and epigastric pain. As in pharyngoesophageal diverticula, pulmonary symptoms are often present but underestimated. These symptoms range from mild nocturnal cough to life-threatening massive aspiration.

**DIAGNOSIS**

The diagnosis is suggested by a posterior mediastinal air-fluid level on chest roentgenogram and is confirmed by a barium esophagogram. The presence of an associated hiatal hernia or carcinoma within the diverticulum (both uncommon occurrences) can be assessed by endoscopic examination, which should be performed in every case. Esophageal manometry is not essential for the diagnosis but is helpful in defining the nature and the extent of the underlying motor disorder. Manometry may require directed passage of the catheter beyond the diverticulum if difficulty is encountered.

**INDICATIONS FOR SURGERY**

Most would agree that surgical intervention is necessary in symptomatic patients, those with large diverticula, and those with established complications such as bronchopulmonary infection (Fig. 22.5). The indication for surgery in asymptomatic or minimally symptomatic patients is less clearly defined in the literature, and yearly surveillance for patients with an asymptomatic thoracic esophageal diverticulum is often the most prudent option.
The basic elements of the operation are resection of the diverticulum and a myotomy to alleviate the underlying motor disorder. Although some authors advocate that a myotomy can be done only if a documented underlying motor disorder is present, this is a hazardous proposition because it risks the integrity of the diverticulectomy staple line in the postoperative period and a possible recurrence of the diverticulum later. Another point of controversy is the length of the myotomy. Although a limited myotomy may be satisfactory in many situations, a long myotomy from the level of the aortic arch down to the first 1 to 2 cm of the stomach adds little to the duration of the operation and essentially eliminates the need for reoperation. Naturally, once the cardia is mobilized, a nonobstructive type of antireflux repair must be added to avoid the almost certainly ensuing gastroesophageal reflux, which the aperistaltic esophagus cannot adequately clear.

**SURGICAL PROCEDURE**

All patients receive a preoperative dose of a second-generation cephalosporin, and this antibiotic is continued for 24 hours postoperatively. Patients with large diverticula should have the contents of the sac evacuated by a large tube preoperatively. Rapid sequence induction of general anesthesia is necessary to secure rapid control and protection of the airway against aspiration.

Notwithstanding that most diverticula project into the right side of the chest, the preferred approach for an epiphrenic diverticulum is through a left thoracotomy, which permits excellent exposure of the lower half of the thoracic esophagus, the diverticulum, and the cardia should an antireflux repair be necessary. The patient is placed in the right lateral decubitus position, and the left chest is entered through the sixth intercostal space. The use of a double-lumen endotracheal tube with deflation of the left lung greatly improves the exposure. The mediastinal pleura is incised over the esophagus from the aortic arch to the esophageal hiatus. The esophagus, including both vagus nerves, is mobilized at some distance away from the diverticulum and encircled proximally and distally with Penrose drains (Fig. 22.6). The sac is freed from the surrounding mediastinal structures with blunt and sharp dissection. Occasionally, the sac is firmly adherent to the right lung or the right mainstem bronchus (in midesophageal diverticula), and upward traction on the esophagus allows a careful dissection of the sac from those attachments.

The sac may be invested in an inflammatory rind of tissue, and this must be carefully removed to expose the wall. The neck of the diverticulum is sharply dissected from the surrounding esophageal muscle and residual scar if present, and the mucosal layer should be separated from the surrounding overlying muscle at its margins so that the true neck is obvious for later division. The vagus nerves may be very adherent to the sac and can be embedded in the inflammatory tissue surrounding it. Care must be taken not to injure the nerves during this part of the procedure.

Dissection then proceeds caudally to mobilize the gastric cardia. The phrenoesophageal membrane is sharply divided, and the hiatus is manually dilated. The mobilization of the cardia is completed by dividing the posterior attachments between the two vagi and entering the lesser sac, followed by complete excision of the fat pad in this region just superior to the cardia. The posterior attachments here may harbor an enlarged arterial branch emanating from the left gastric artery, and failure to recognize this can result in hemorrhage.

At this time, a 44F or larger bougie is placed by the anesthesiologist with
manual guidance by the surgeon past the diverticular opening. The diverticulum is then brought into view by grasping its fundus with an atraumatic clamp and rotating the diverticulum and the esophagus anteriorly and then to the left (Fig. 22.7). If possible, a diverticulectomy is now performed by excising the sac about 5 mm from its neck using a linear stapling device. If this is not possible due to the size of the neck or necrosis at its junction at the esophageal wall, it can be sharply excised after placement of stay sutures on the cranial and caudal extents of the neck. This can then be repaired using interrupted 3-0 absorbable sutures. A nasogastric tube is passed, and the stapled closure is tested for leak by air insufflation under water with distal esophageal compression. The muscle layer is then approximated over the mucosal closure with interrupted 3-0 silk sutures (Fig. 22.8). On occasion, the muscular layer may be too edematous or attenuated for a good second-layer closure. If this is the case, an intercostal muscle flap may be mobilized and approximated to the linear repair using interrupted small silk sutures on the muscular margins. A long myotomy is then performed on the left lateral aspect of the esophagus 180 degrees from the excised diverticulum. The muscle is divided at least 2 cm proximal to the diverticular repair, and if feasible from just below the aortic arch and carried across the gastroesophageal junction onto the stomach for approximately 1 cm. The edge of the muscle is gently dissected off the underlying mucosa for several millimeters on either side to preclude premature healing of the myotomy. A nonobstructive anti-reflux repair should then be performed to prevent reflux sequelae. Our repair of choice is the Belsey Mark IV partial fundoplication, with sutures placed on either side of the myotomy in the muscular layer. Once the second layer of the sutures is placed, the cardia is gently repositioned into the abdomen and the second layer of the sutures is tied (Fig. 22.9). The crura are reapproximated with large nonabsorbable suture so that it will accommodate just the tip of the operator’s index finger, and the nasogastric tube is advanced into the stomach.

Minimally invasive operations for thoracic esophageal diverticula have been reported. For mid esophageal diverticula, right video-assisted thoracoscopic surgery (VATS), diverticulectomy with an endo-GIA stapler, closure of the overlying muscle over the staple line, and myotomy opposite the diverticulectomy site are feasible.

In: Shields TW, ed. General Thoracic Surgery. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:1975–1986).

The preferred minimally invasive approach for epiphrenic diverticula involves laparoscopy, esophagogastric myotomy, stapled diverticulectomy, and partial fundoplication (Toupet or Dor). Surgical series from centers with extensive experience in minimally invasive antireflux surgery and esophagectomy have demonstrated reasonable symptomatic outcomes and morbidity and mortality, which are comparable to large open surgical series. These minimally invasive techniques are attractive. A recent series of laparoscopic repair of epiphrenic diverticula demonstrated a median length of stay of 3 days, which is certainly shorter than that reported in large series of repair via left thoracotomy. However, it bears repeating that the diverticula of the thoracic and epiphrenic esophagus are quite rare and, thus, a typical thoracic surgeon may only treat a handful of them in his entire career. It is unlikely that one can extrapolate the results obtained at centers with extensive experience in minimally invasive esophageal surgery to the thoracic surgical community at large, and open surgical repair remains the gold standard in our opinion.

SURGICAL COMPLICATIONS AND POSTOPERATIVE CARE

Retention of the nasogastric tube for 3 to 4 days is encouraged, at which time a barium esophagram is performed to rule out leak at the repair or myotomy or mechanical obstruction. If no leak is present, a clear liquid diet is begun and is rapidly advanced to a soft mechanical diet with discharge typically on the sixth or seventh postoperative day. Although success rates are very high, there has been moderate morbidity reported and a mortality of up to 9% in some series, substantiating the recommendation that small or asymptomatic diverticula should be observed. Causes of death include mediastinitis as a result of esophageal leakage and aspiration pneumonia. Morbidity and mortality are obviously negatively influenced by the advanced age of many candidates.

SUGGESTED READINGS

By far the most common diverticulum of the esophagus is the pharyngoesophageal, or Zenker’s, diverticulum, which, as the authors point out, is not a true diverticulum because it is a mucosal protrusion, not a true full-thickness outpouching of the esophagus. Most commonly, these patients present with difficulty swallowing, noisy swallowing, and often signs and symptoms of aspiration, especially at night. Many of these patients are elderly, and many are told that they are not operative candidates because of the risk. It is safe to say that the risk is minimal, and it is likely that there is far greater risk to the patient by allowing the diverticulum to remain, especially if the patient has signs of aspiration. If the patient is felt to be at significant risk for general anesthesia, the procedure may be carried out under local anesthesia.

It has been and remains our preference to approach a Zenker’s diverticulum via the open technique though I have been pleased with outcomes when we have employed the endoscopic technique. This open procedure involves an incision along the anterior border of the left sternocleidomastoid muscle with dissection down to the prevertebral fascia. The left side is used even if the diverticulum protrudes to the right because the esophagus is easily mobilized and the left recurrent nerve is less at risk than the right. Often the diverticulum in the anesthetized patient appears smaller than what the surgeon originally thought and sometimes is difficult to identify. The myotomy is begun at the base of the diverticulum at Killian’s triangle and carried well down onto the esophagus taking care to incise both the longitudinal and circular muscle fibers. For all but the largest diverticula, I prefer to perform a diverticulectomy, excluding the diverticulum from the flow of material in the esophagus but avoiding a mucosal entry. If a diverticulectomy is to be carried out, a large (50F) bougie is placed to avoid tenting of the mucosa and excessive excision that could lead to a stenosis. A staple line is placed across the diverticulum, and the patient is not fed for several days. A contrast study assures integrity of the staple line before feeding.

As described by the authors, an endoscopic approach to the treatment of Zenker’s diverticulum has been described. An instrument specifically for this purpose, the Weerda diverticuloscope, should be used for proper visualization of the diverticulum and endoscopic stapler placement. One blade of the stapler must be in the esophageal lumen and the other in the lumen of the diverticulum for the procedure to be successful. This accomplishes obliteration of the “party wall” between the diverticulum and the lumen of the esophagus and accomplishes a myotomy. The long-term results of this procedure confirm that this approach offers an excellent alternative for many patients. Its utility is limited in those patients who have limited neck extension.

It is critical to recognize that any esophageal diverticulum or pseudodiverticulum represents the manifestation of a motor disorder of the esophagus, which underscores the importance of a complete myotomy. The myotomy is especially important if the diverticulum has been excised to assure the integrity of the staple line. The terms “pulsion” and “traction” diverticula are rarely used in the present-day nomenclature. Even the so-called epiphrenic diverticula are manifestations of a motor disorder, and when the operation is indicated a myotomy must also be performed. I agree with the authors that a long myotomy beginning just inferior to the aortic arch and extending down onto just distal to the gastroesophageal junction is preferred. Patients with an epiphrenic diverticulum are also subject to aspiration, but many, if not most, patients with these diverticula do not require operation. Most are asymptomatic and merely represent curiosities on plain chest radiographs or barium contrast studies. The mere presence of a large epiphrenic diverticulum is not an indication for operation, especially because these must be approached via a thoracotomy or VATS procedure.

**EDITOR’S COMMENTS**

By far the most common diverticulum of the esophagus is the pharyngoesophageal, or Zenker’s, diverticulum, which, as the authors point out, is not a true diverticulum because it is a mucosal protrusion, not a true full-thickness outpouching of the esophagus. Most commonly, these patients present with difficulty swallowing, noisy swallowing, and often signs and symptoms of aspiration, especially at night. Many of these patients are elderly, and many are told that they are not operative candidates because of the risk. It is safe to say that the risk is minimal, and it is likely that there is far greater risk to the patient by allowing the diverticulum to remain, especially if the patient has signs of aspiration. If the patient is felt to be at significant risk for general anesthesia, the procedure may be carried out under local anesthesia.

It has been and remains our preference to approach a Zenker’s diverticulum via the open technique though I have been pleased with outcomes when we have employed the endoscopic technique. This open procedure involves an incision along the anterior border of the left sternocleidomastoid muscle with dissection down to the prevertebral fascia. The left side is used even if the diverticulum protrudes to the right because the esophagus is easily mobilized and the left recurrent nerve
Following the initial report of human lung transplantation by Dr. James Hardy in 1963 at the University of Mississippi, numerous subsequent attempts failed until the first successful transplant by Dr. Joel Cooper at the University of Toronto in 1983. In the succeeding years, lung transplantation has become a viable and effective treatment for patients with end-stage lung disease and has been performed in more than 32,000 recipients worldwide. Progress has been made in surgical techniques, donor lung preservation, lung reperfusion protocols, perioperative care, and long-term medical management of this challenging patient population. These refinements in care are reflected in survival improvements. One-year survival reported by the Organ Procurement and Transplantation Network (OPTN) has improved from 77% in 1997 to 82% in 2007. Likewise, the International Society of Heart and Lung Transplantation (ISHLT) Registry indicated that the median survival increased from 4.0 years if transplanted in 1994, to 5.7 years for a recipient after the turn of the millennium. In fact, the era of a particular transplant procedure remains one of the best predictors of survival in the ISHLT Registry. Similar improvements in survival have occurred in the experience of the Duke Lung Transplant Program (Fig. 23.1A). In the most recent 6-year cohort, our 30-day and 5-year survivals exceeded 97% and 65%, respectively.

Death early after transplant is commonly related to primary graft dysfunction (PGD) that is usually caused by ischemia-reperfusion injury. PGD rates have substantially decreased with better lung preservation and controlled reperfusion strategies. Although posttransplant recipient and allograft survival have significantly improved recently, long-term survival continues to be less than that for other solid organ transplants. Current 5-year survival from the ISHLT Registry approaches 55% for lungs, compared to 73% for cardiac recipients. Late deaths are most frequently related to chronic allograft dysfunction, the causes of which are related to both immunologic and nonimmunologic factors. The control of these factors with better immunosuppressive regimens and with minimizing nonimmunologic injury such as gastroesophageal reflux-related aspiration into the tracheobronchial tree appears to be improving long-term survival.

## INDICATIONS FOR LUNG TRANSPANTATION

Lung transplantation has been successfully applied as a treatment for patients with a number of different end-stage lung diseases. While specific listing criteria and indications have been widely reported, lung transplantation is typically performed in patients (1) with a limited life expectancy secondary to lung failure, estimated to be 6 to 12 months; (2) with the capability of tolerating and following the complicated posttransplant medical regimen; and (3) without comorbidities that would significantly impact posttransplant survival and quality of life, such as concurrent/recent malignancy, extrathoracic infection, or significant other organ dysfunction/failure. In select patients, concomitant other organ transplant or reparative cardiac procedures can be performed with acceptable results.

The choice to perform a single versus a bilateral, sequential lung transplant depends upon multiple factors. Clearly, recipient characteristics such as comorbidities and underlying diagnosis play an important role in directing operative selection. Likewise, the value of increasing the number of recipients transplanted by performing two single-lung transplants (SLTs) from a single donor must be balanced with the benefit of improved long-term survival that is seen in bilateral lung transplants (BLT). While the majority of nonseptic lung disease, such as chronic obstructive pulmonary disorders (COPD), idiopathic pulmonary fibrosis (IPF), and primary pulmonary hypertension, can safely undergo single-lung transplantation, patients with septic lung disease, such as bronchiectasis from either cystic fibrosis (CF) or noncystic causes, require bilateral lung transplantation to prevent infectious complications emanating from the residual native lung. Because of the numerous complications arising from the native lung such as infection, hyperinflation, malignancy, and a 25% absolute difference in survival at 7 years (Fig. 23.1B), the practice of the Duke Lung Transplant Program has been to perform bilateral, sequential lung transplants in the majority of patients. This chapter describes the steps in procuring, preparing, and transplanting lungs in a bilateral, sequential fashion. These techniques are also utilized when only one lung is being transplanted.

## DONOR LUNG RETRIEVAL

The improved outcomes after lung transplantation have led to an increased number of recipients waiting for transplant. In the United States, approximately 4,000 patients are listed and waiting for lung transplant. Annually, approximately 1,100 lung transplants are performed while 450 deaths occur on the waiting list. The shortage of organs is not unique as compared to other organs, but there are a number of differences. Of organs commonly transplanted, the lungs are the most sensitive to exogenous damage. Events prior to brain injury, such as smoking, and events associated with brain injury, such as aspiration, mechanical ventilation, or neurogenic pulmonary edema, may compromise the suitability of the donor lungs for transplantation. However, there is a wide variety of opinions regarding what is a suitable lung for transplantation. Throughout the United States, there has been a gradual increase in the percentage of organ donors in which lungs were retrieved to 17%. However, this number is substantially less than the best-performing regions in the United States as well as in Australia, where the utilization is 40% to 50%. Moreover, survival rates for recipients from these high-utilization
regions exceed registry data. Aggressive donor management with hormone replacement, particularly with respect to corticosteroid administration, appropriate ventilatory settings with alveolar recruitment measures, suitable fluid resuscitation with vasoactive drug administration, aspiration prevention, and utilization of bronchoscopic suctioning have been shown to increase the yields of donor lungs. Importantly, aggressive evaluation and placement strategies by transplant centers are also factors in increasing donor lung yield.

Emerging technologies will also allow for an expanded donor pool and better utilization rates. For example, ex vivo lung perfusion (EVLP) has recently been initiated for human lung transplantation. An initial manuscript detailing 35 lungs transplanted following EVLP suggests equal outcomes in terms of PGD, BOS development, and 1-year survival when compared to 116 control recipients. Currently, this technology allows for rehabilitation of some lung allografts otherwise thought to be unusable. However, in the future it may provide a method for actually improving long-term outcomes through gene therapy or other treatments.

The donor lungs must (1) be ABO compatible with the recipient’s; (2) have no unacceptable HLA antigens if the recipient has anti-HLA antibodies as determined by prospective or virtual cross matching techniques; (3) not transmit diseases such as hepatitis B or C, HIV, or malignancies; (4) be size compatible; and (5) be able to function physiologically to immediately sustain cardiopulmonary function in the recipient. With respect to disease transmission, donors who test as serologically positive for hepatitis B, hepatitis C, or HIV, or have non-CNS, nonskin malignancy (excluding melanoma) are not used except in extraordinary circumstances. One exception is that donors with positive hepatitis core antibody, but negative surface antigen serologies, can be used with very low rates of disease transmission.

Donor evaluation includes the collection of a thorough medical history for the potential donor. Specific donor criteria vary according to individual transplant centers, but in general, the focus is on the donor’s blood type, size, age, smoking habits, pulmonary diseases, thoracic procedures, and mode of death. Additional information that should be provided at the time of a donor offer includes radiographic findings, arterial blood gas, ventilator settings, peak airway pressures, endotracheal tube size, and bronchoscopic findings. In an older donor with a substantial smoking history, a high-resolution chest CT can greatly assist in evaluating the lung parenchyma and allow for a better assessment of the presence of emphysema, lung nodules, and interstitial lung disease that would be contraindications to the use of the lungs. Corticosteroids (methylprednisolone 1,000 mg) should be administered to the donor and ventilatory settings should be optimized. Underventilation and inappropriate use of positive end-expiratory pressure (PEEP) is common and optimization can improve the donor arterial blood gas results. The most recent chest radiograph should be examined for pathology and can be used to help with sizing of the organs. Atelectasis is the most common reversible cause of low PaO2/FiO2 ratios in the donor. On-site evaluation of prospective donors greatly increases the number of lungs retrieved. In the absence of poor airway compliance (elevated peak airway pressure in the absence of a small endotracheal tube or morbid obesity) or combined abnormalities such as an older donor with extensive tobacco exposure and marginal arterial blood gases, we attempt to evaluate all donors.

Size matching of the donor and the recipient is initially based on height. Matching within 4 inches between donor and recipient is usually without consequence. However, recipients with obstructive lung disease will have larger than normal thoracic cavities, and larger donors are preferred. Recipients with restrictive lung disease, on the other hand, will have smaller than normal thoracic cavities, and smaller donors are preferred. Comparison of chest measurements, both vertical and horizontal dimensions, between donor and recipient from the chest X-ray provides additional information regarding sizing. It is important to account for size reformatting with digitized films. While significant size differences between donor lung size and recipient thoracic volume can be managed successfully in the operating room through the use of pneumoreduction techniques, appropriate size matching prior to committing to the transplant procedure is optimal.

Fiberoptic bronchoscopy is performed to evaluate for evidence of airway inflammation, intraluminal pathology, anatomic abnormalities, as well as to remove secretions from the airways. While it is common to encounter some purulent secretions,
this is not a contraindication to organ utilization unless the secretions do not clear or they recur after being suctioned clear. Donor airway cultures and gram stains are important for determining recipient antibiotic administration, but should not obviate the utility of lungs from donors.

Donor lung procurement is usually performed in the context of cardiac and hepatic organ procurement. The following donor procurement procedure can be utilized in all circumstances. Exposure of the thoracic and abdominal organs is through a median sternotomy with an extension of the incision in the midline to the pubis. The pericardium is opened in the midline with wide extensions laterally at the level of the diaphragm inferiorly. Pericardial stay sutures are placed for exposure. Both pleural spaces are opened widely, extending from the diaphragm inferiorly to the mammary pedicles superiorly. Adhesions are divided with the electrocautery. Manual examination of both lungs is performed serially to assess the general appearance, nodules, atelectasis, consolidation, edema, and compliance. Suspicious findings should be excised and sent for pathologic analysis to rule out malignancy. The elastic recoil of the lungs is then determined by inflating the lungs with bagged breaths and allowing the lungs to deflate independently by temporarily disconnecting the endotracheal tube from the ventilator. Lungs with adequate compliance should rapidly deflate following disconnection from the ventilator. During this phase of the evaluation, an aggressive alveolar recruitment is performed. Working with the anesthesiologist, the lungs are hand ventilated to expand any atelectatic areas. An arterial blood gas is obtained following these maneuvers. We use a minimum PaO2 of 300 mmHg with the FiO2 of 1.0 and PEEP of 5 cm H2O as criteria for suitability. Additional information can be obtained and nonpulmonary shunt causes of impaired oxygenation can be identified by individually sampling from the four pulmonary veins. The expected PaO2 should be greater than 400 mmHg from the veins draining appropriately functioning regions. This approach can identify areas of lung inappropriate for transplantation. Not infrequently, confused segments or areas of consolidation can be resected by wedge resection, lobectomy, or the use of only one lung. These resections are ideally done as a “back table” procedure after the procurement. Similarly, when the donor lung is oversized for the recipient chest cavity, lung resection can be performed, again, preferably as a back table procedure. In these situations, our preference is to perform a middle lobectomy on the right and a lingulectomy on the left, with a curvilinear wedge resection from the anteroposterior section of either upper lobe. When even greater oversizing occurs, implanting only the lower lobe may be optimal.

Once the decision that the donor lung(s) is suitable for procurement is confirmed and this is communicated to the recipient surgical team, preparation for procurement begins by mobilizing the great vessels. Using primarily cautery dissection, the ascending aorta is dissected from the pulmonary artery (PA) and the superior vena cava (SVC). The SVC is mobilized by cautery dissection from the innominate vein to the right atrial junction. This dissection is continued on to the heart to develop Waterston (interatrial) groove. By fully mobilizing the SVC and adequately developing the interatrial groove, the two most common sites of procurement injury can be minimized: (1) injury to the right PA posterior to the SVC often at the level of the right PA trunk bifurcation, and (2) an inadequate anterior right-sided left atrial cuff. The inferior vena cava (IVC) can usually be mobilized quickly with finger dissection. Commonly, temporary hemodynamic instability occurs, but can be lessened by placing the donor in Trendelenburg position prior to these maneuvers. The IVC should be well exposed below and above the diaphragm to ensure adequate tissue for abdominal and cardiac transplant teams.

The trachea is located by incising the posterior pericardium after gently retracting the SVC laterally and the aorta medially. An umbilical tape can be used to encircle the trachea after the plane is developed manually. Once all procuring teams are ready to cannulate, the donor is fully heparinized (250 units/kg). The ascending aorta is cannulated for standard antegrade cardioplegia. The cannula is secured using a 4-0 prolene mattress or purse-string suture and a Rummel tourniquet. Placement of the PA cannula occurs in a similar fashion as the aortic cannula with placement comfortably distal to the pulmonary valve, but adequately proximal to assure equal perfusion through both pulmonary arteries. Care should be taken to ensure that the bent tip of the curved cannula is directed toward the bifurcation of the PA. After placement of the cannulae, a 500-µg bolus dose of prostaglandin E1 (prostacyclin) is administered directly into the pulmonary trunk, near the pulmonary cannula. Immediately following infusion of the prostacyclin, the SVC is ligated doubly or occluded using a vascular clamp and the IVC is divided allowing decompression of the right heart. The IVC should be divided above the pericardial reflection to provide adequate cuff for both the liver and heart implantations. The aorta is cross-clamped and the cardioplegia solution is infused through the aortic cannula. Even if the heart is not to be procured, aortic cross-clamping should be performed to prevent bronchial artery flow. Left heart decompression is achieved by performing a large left atrial appendage incision. Once this incision is created, perfusion of the lungs through the PA catheter is initiated with either Perfadex® or Celsior® preservation solutions (extracellular-based solutions). The height of the solution bag above the PA cannula should not be more than 30 inches. Approximately 3 L of perfusate (35 to 50 ml/kg) are flushed through the PA (antegrade flushing of the lungs). Upon commencing perfusate flow, the thoracic cavity should be bathed in iced saline solution. The procuring surgeon then assesses biventricular filling by directly palpating the heart. Exsanguination and subsequent flow of clear fluid from the left atrial appendage should be observed, as it usually indicates successful antegrade flushing of the preservation solution throughout the pulmonary vasculature. Ventilation of the donor lungs should continue during preservation solution administration. To optimize visibility for the subsequent organ removal, the abdominal IVC should be vented inferiorly and not into the chest.

Following adequate infusion of the appropriate preservation solutions into the aorta and the PA, removal of the heart is performed. It is paramount that adequate tissue for implanting be achieved for both the heart and lung allografts. The heart is retracted to the right and a left atriotomy is initiated midway between the coronary sinus and the left pulmonary veins. The interatrial groove on the right is further developed to ensure adequate atrial cuff size. The initial atriotomy is extended inferiorly and superiorly by scissors, while being mindful of the left pulmonary veins. The surgeon on the left side of the table typically has the optimal view of the right pulmonary vein orifices and should finish creating the atrial cuff while directly visualizing these orifices. Enough cuff width should be available for the left atrial anastomosis. The SVC is divided between the silk ligatures, or by using a vascular clamp one can maximize the length of SVC taken by repositioning the clamp distally at this time. The main PA is transected at the bifurcation and the aorta is divided proximally to the cross-clamp. As with the SVC,
the vascular clamp may be moved distally in order to maximize the length of the aorta. The heart is removed from the field. After the heart is passed off the table, retrograde flushing of the lungs is performed through each large pulmonary vein orifice. Adequate retrograde perfusion can be determined when the perfusate eluting from the PA becomes clear. Usually this requires approximately 1 to 2 L of the preservation solution (250 to 500 ml of solution for each of the four pulmonary veins). Removal of the remaining thoracic contents ensues by dividing the inferior pulmonary ligaments and posterior attachments. The trachea is mobilized by blunt dissection to at least three cartilaginous rings proximal to the carina. Prior to stapling the trachea, the anesthesia team ventilates the lungs with several bagged breaths. The endotracheal tube is pulled proximally, the lungs are allowed to deflate to approximately two-thirds of vital capacity, and the trachea is stapled with the TA-30 stapler two to three rings above the carina. A second row of staples is immediately placed proximally and the trachea is divided between the two staple lines with a scalpel or scissors. Over-expansion of the lungs is avoided to prevent alveolar stretch injury and subsequent allograft failure.

Heavy scissors can now be used to swiftly divide the remaining posterior mediastinal tissue inferiorly and superiorly in the plane anterior to the esophagus, completely freed the lungs for removal. Alternatively, the esophagus can be divided after removal of the nasogastric tube proximally and distally with a GIA stapler. The remaining dissection then occurs between the esophagus and the spine with subsequent removal of the lungs en bloc with the esophagus. At this point, they can be bagged together for travel; if the right and the left lungs are going to separate institutions, they require division at the procurement hospital. Our preference is to perform back table dissection at the implanting hospital when possible because of better lighting and equipment.

The lungs are divided by incising the posterior pericardium, the left atrium midway between the two sets of veins, and the main PA at its bifurcation (Fig. 23.2). When lungs are traveling to separate institutions, the left bronchus can be transected between staples just distal to the carina to maintain its inflation pressure for transport. Upon arrival at the transplanting institution, the grafts are prepared for implantation. This primarily involves dividing the main bronchi for each lung either one or two rings proximal to the upper lobe takeoff. Because of the reliance of the bronchi and airways on collateral perfusion from the PA, the length of the bronchus is kept to a minimum. Care should be taken to minimize dissection along the length of the bronchus. The pulmonary arteries are inspected for the presence of pulmonary emboli. If present, they are removed with forceps and retrograde flushing through the pulmonary veins is repeated until the perfusate clears. All structures are inspected for injuries. Reconstruction of vascular injuries or inadequate cuff lengths is best achieved on the back table before initiating implantation. Direct repair is usually possible, but autologous tissue from the explanted lungs, allograft tissue from the donor, and pericardium from the recipient can be used to repair injuries. The arteries and atrial cuff should also be evaluated for residual pericardial attachments, and these should be removed at this time. If retained they may lead to kinking and blood flow occlusion after the anastomosis is completed. Samples of donor bronchus for microbiologic testing can also be taken at this time.

**RECIPIENT PROCEDURE**

**Anesthetic Considerations**

Suitable large-bore intravenous access is required for potential large volume fluid administration. All recipients have a radial artery catheter and a PA catheter placed via an internal jugular vein. We also routinely place a femoral arterial catheter because of the frequent poor functioning of the radial arterial line, particularly with clamshell incisions. Patients are intubated with a double-lumen endotracheal tube with the tip placed into the left bronchus. Confirmation of tube placement is made by fiberoptic bronchoscopic visualization. In small recipients in which a 37F or greater double-lumen tube cannot be placed, single-lumen intubation is done with the plan to perform the majority of the procedure on cardiopulmonary bypass (CPB). While others have used single-lumen tubes using bronchial blockers to isolate the left lung and advancement of the tube into the left bronchus to isolate the right, we prefer using CPB to avoid airway complications such as tube occlusion from inspissated mucus. When performing SLT, it is preferable to transplant the side that has a normal pleural space and the worst function as determined by quantitative perfusion. All transplants are done with the availability of CPB for the transplant procedure and extracorporeal membrane oxygenation (ECMO) for posttransplant support if necessary. During the procedure, minimal fluids—particularly crystalloid solutions—are administered while inotropic agents (epinephrine) are used liberally to maintain appropriate hemodynamics. Communication by the surgeons to the anesthesiologists prior to retracting on cardiovascular structures that will cause hemodynamic compromise greatly aids in the appropriate administration of boluses of vasoactive agents to prevent hemodynamic compromise. Maintenance of an appropriate red blood cell volume and clotting factors throughout the procedure is paramount. This is especially important in patients with substantial bleeding and those with pulmonary hypertension and passive hepatic congestion. We routinely use transesophageal echocardiography (TEE) to monitor cardiac function and filling, as well as to interrogate the left atrial anastomoses.

**Positioning of the Patient and Skin Incision**

For left SLTs, the recipient is placed in a right lateral decubitus position, with access to the left groin for possible femoral vein cannulation. The procedure is performed through a standard fifth intercostal space (ICS) posterolateral thoracotomy. Muscle-sparing thoracotomy can be utilized, particularly for patients with COPD. Right SLTs can either be performed through a standard fifth ICS posterolateral thoracotomy or preferably, through a fourth ICS anterolateral thoracotomy. Access for CPB cannulation can be achieved most easily in the chest and the groins are not exposed. For patients undergoing a bilateral lung transplant, we use a bilateral fourth ICS antero-transsternal thoracotomy (clamshell) incision (Fig. 23.3).
The patient is placed in a supine position, and both arms are lifted anteriorly and abducted. The forearms are rested on cushioned support as the arms are flexed slightly at the level of the elbow. A warming blanket or device is routinely used and is positioned from the umbilicus down for right and bilateral transplants and from the thigh down for left lung transplants. It is imperative that the patient’s chest and upper abdomen are prepped widely. For a female patient, the skin incision is made at or below the infra-mammary crease, and the chest is opened through the fourth ICS after a breast flap is developed and retracted superiorly on each side. After ligating the internal mammary pedicles, we routinely divide the sternum transversely. While we have had a low incidence of sternal complications, other groups have reported more sternal wound problems and preferentially perform the procedure without division of the sternum through separate bilateral anterolateral thoracotomies. At this point, it is important to divide the mediastinal pleura superior to the level of the mammary vein and inferior to the level of the pericardium with cautery. The pericardium remains intact at this point, but may be opened if the use of CPB is anticipated. Prior to widely opening the retractors, the intercostal muscles in the fourth ICS are divided in the lateral and posterior direction in order to maximize the overall exposure with the clamshell incision. The overlying muscles (e.g., latissimus dorsi and serratus anterior) are relatively spared laterally. Adhesions are routinely encountered and are particularly prevalent in patients with CF, previous pneumothoraces, or previous pulmonary resections. The adhesions located along the chest wall, diaphragm, and to the mediastinum well anterior to the phrenic nerve should be divided using electrocautery. Dissection of mediastinal adhesions in the area of the phrenic nerve should be done sharply and with great caution. Following lung reduction surgery or previous lobectomies, adhesions to the mediastinum may be such that the phrenic nerve cannot be identified. In these circumstances, it is often prudent to divide the overlying lung tissue using a GIA stapler and to leave a small amount of residual lung to prevent phrenic nerve injury. This is usually accomplished after all other aspects of the pneumonectomy have been performed. Frequently, this is the most time-consuming portion of the operation.

In recipients with small chest cavities such as most patients with IPF, a figure-of-eight traction suture (0-silk) is placed into the fibrous dome of the diaphragm, and this suture is brought out of the chest using a crochet hook passed through a 14-gauge angiocatheter placed in the most inferolateral aspect of the pleural cavity. The diaphragm is retracted inferiorly while pulling down with the suture, and the suture is secured external to the chest wall with a small clamp. To aid in the exposure of the left hilum, a heavy silk retraction stitch is placed inferiorly on the pericardium, posterior to the phrenic nerve, and anterior to the inferior pulmonary vein. The silk suture is passed through a heavy-duty Rummel tourniquet, fashioned from a red rubber catheter, thus allowing the heart to be safely retracted upward and to the right to provide improved exposure during further dissection of the hilar structures and implantation of the donor lung. For bilateral lung transplants, we routinely mobilize (but not divide) both hilar structures completely before initiating the recipient pneumonectomy. Which pneumonectomy is done first is dependent on several factors listed in the relative order of importance: (1) normal chest cavity size and configuration; (2) donor lung quality (a donor lung with contusion, consolidation, or procurement injury is done second); (3) worst native lung function (this side should preferentially be done first); and (4) degree of technical difficulty for each side (more technically difficult side, usually the left, should be done first, which shortens the period in which only one transplanted lung is being perfused).

The recipient pneumonectomy differs from conventional pneumonectomies in that intrapericardial dissection is always done, division of the PA is done at or beyond the takeoff of the branch vessels, and the bronchus is divided immediately proximal to the upper lobe orifice. The use of the Endo GIA stapler facilitates the ligation and division of the pulmonary arteries and the pulmonary veins. After the lung is removed, the pericardium around the hilar structures is circumferentially incised. Development of Waterston groove on the right side, division of attachments from the roof of the left atrium to the PA and the posterior left atrial wall and pericardium facilitate subsequent left atrial clamp placement (Fig. 23.4). The pulmonary arteries are mobilized proximally. On the right side, this requires division of attachments anteriorly to the SVC. On the left side, attention to avoiding recurrent laryngeal nerve injury is paramount. Particularly in the anterosuperior portion of the left PA, the use of electrocautery is avoided. It is important to establish hemostasis, especially in the posterior mediastinum prior to initiating lung implantation. Particularly in patients

![Fig. 23.3. Positioning and incision utilized for the clamshell incision. The patient is placed in a supine position with the arms lifted anteriorly and abducted. The forearms are rested on cushioned support as the arms are flexed slightly at the level of the elbow. A warming blanket is placed to cover the lower body below the level of the umbilicus. For a male patient the incision is performed at the level of the fourth intercostal space.](image-url)
with CF and sarcoidosis, bleeding from lymph nodes can be problematic. Wide extirpation of these lymph node groups with clipping of the bronchial arteries and other source vessels provides excellent hemostasis, improves exposure, and can assist in preventing vascular anastomotic complications. The vagus nerve located posterior and lateral to the right-sided lymph node group should be identified and protected.

In patients undergoing bilateral lung transplantation, once hemostasis and adequate lengths of PA, left atrium, and bronchus are achieved, two sets of figure-of-eight #1 Maxon pericostal sutures are placed in the posterior and lateral aspect of the thoracotomy wound in preparation for closure of the chest at this point of the operation because of the excellent exposure obtained while the lung is out of the pleural cavity. Similarly, posterior pleural drainage tubes are placed in the costovertebral gutter. We use a 36F right-angle chest tube and a 24F flexible Blake drain. A smaller caliber suction catheter placed into this chest tube and connected to suction facilitates the drainage of blood and fluid throughout the remainder of the case. A flexible drainage tube can also be placed at this time in the axillary space, between the rib cage and the latissimus muscle. In female patients, the tip of this catheter can later be guided into the submammary space near the end of the operation.

Cardiopulmonary Bypass

Most lung transplants can be performed safely and efficiently without the use of CPB. However, CPB should be used whenever recipient hemodynamics, poor systemic perfusion, or technical factors dictate. We use CPB on a planned basis for patients (1) with severe pulmonary hypertension, although occasionally some patients have been done without bypass with usage of nitric oxide and inotropic support; (2) requiring intracardiac procedures such as ASD/VSD closure, valve repair; (3) with a small recipient airway; (4) who are large relative to the donor lung to avoid full cardiac output through a small vascular bed; and (5) with fragile left atrial tissue or inadequate donor left atrial cuff, to allow the anastomoses to be performed without clamps using either cardioplegic arrest or fibrillatory arrest. Particularly for patients with pulmonary hypertension and presumed passive hepatic congestion, the bypass circuit is primed with fresh frozen plasma to mitigate peritransplant coagulopathy. For right and bilateral lung transplants, cannulation is performed in the chest using the right atrial appendage for placement of a 120-degree double-stage cannula for venous return and ascending aorta cannulation for arterial return. For left lung transplants, femoral venous cannulation is done with a long Bio-Medicus venous (15 to 23F) catheter for venous return with descending aorta cannulation for arterial return. Frequently, the femoral venous cannulation is difficult in the decubitus position. In urgent situations venous return can be achieved by cannulating the left PA that allows more time to achieve either femoral venous access. Alternatively, we have been able to access the right atrial appendage following initiation of CPB. While CPB can be performed at any point in the operation as needed, our preference is to perform as much of the dissection including a pneumonectomy prior to initiating bypass. When CPB is utilized, we perform both pneumonectomies and full mobilization of all bronchi, pulmonary arteries, and left atrial cuffs before initiating any portion of the implant procedure.

Lung Implantation

There is little difference between the implantation of the left or right lung. Usually, the left lung implantation is slightly more difficult when performing a bilateral lung transplant because the heart and left atrial appendage impede the exposure for the left atrial anastomosis. Heparin is administered through a central vein (100 U/kg) with a goal ACT of approximately 300 seconds. The recipient main stem bronchus is cut with a scalpel just proximal to the takeoff of the upper lobe bronchus. After the cartilaginous portion of the bronchus is divided with a blade, a retraction stitch is placed anteriorly to secure control over the bronchus. The remainder of the bronchial wall (posterior, membranous portion) is then divided with a pair of sharp scissors (Fig. 23.5). The recipient bronchus is now ready for anastomosis, and any secretions within the lumen are aspirated. Confirmation of endotracheal tube location is performed. The pleural space, bronchus, and endotracheal lumen are irrigated with an antibiotic solution. After aspirating the antibiotic solution, iced laparotomy sponges are placed posteriorly in the pleural cavity, and the donor lung is orthotopically positioned in the pleural cavity. The recipient bronchus and donor bronchus are aligned, and the bronchial anastomosis is performed with a 4-0 PDS suture in a running fashion. The posterior membranous portion of the bronchial anastomosis is performed first, starting from one corner of the membranocartilaginous junctions (Fig. 23.6). The anterior cartilaginous portion of the bronchus is anastomosed similarly using the running technique. Usually one bronchus is clearly larger, most commonly the recipient. By placing a transition stitch from the outside of the smaller bronchus into the inside of the larger bronchus, an intussusception is created. The orientation of the anatomy is preserved with membrane-to-membrane and cartilage-to-cartilage apposition with approximately a one-ring intussusception. After completing the bronchial anastomosis, it is evaluated for an air leak under water while the anesthesiologist manually inflates the donor lung with room air.

After completing the bronchial anastomosis, the already stapled recipient PA is occluded proximally with a Satinsky vascular clamp, and the staple line is trimmed away. The donor PA is similarly

Fig. 23.4. Division of the attachments between the left pulmonary artery and superior pulmonary vein and left atrium is initiated laterally and continued medially. Completing the mobilization of the roof of the left atrium from the right side greatly assists in the placement of vascular clamps on the left atrium and subsequent anastomoses.

Fig. 23.5. The bronchus is divided anteriorly with a scalpel and a retraction suture is placed anteriorly to aid in the positioning of the bronchus for the subsequent anastomosis. Shown is division of the membranous bronchus. The excised recipient bronchus is sent for culture studies.
Fig. 23.7. The pulmonary artery anastomosis is performed in an end-to-end manner using a running suture of 5-0 polypropylene suture. Frequently, a substantial size discrepancy exists that can be addressed by elongating the distensible smaller PA and taking numerous bites.

With the last few throws of the 5-0 Prolene suture left loose anteriorly (Fig. 23.9), the vascular clamp on the PA is partially released to allow blood to flow into the newly implanted lung through the PA anastomosis in order to remove air from within the pulmonary vasculature. Immediately prior to tying the 5-0 Prolene suture, the Satinsky clamp on the recipient left atrium is released to force out any residual air. Reperfusion is carefully controlled to minimize the risk of PGD. Controlled, low-pressure reperfusion of the lung is achieved by gradually releasing the PA clamp over 10 to 15 minutes. Ventilation with room air is initiated by hand and then by mechanical ventilation. Pressure control mode of ventilation is preferred with 5 to 8 cm of H2O of PEEP, a distending pressure of 16 to 22 cm of H2O, and minimal FIO2, preferably less than 30%. During this reperfusion period, hemostasis of the donor lung tissue is achieved. At the time of full release of the PA clamp, the PA pressures should be normal. Use of nitric oxide and loop diuretics are initiated if PA pressures are elevated or if poor systemic oxygenation is present. An additional anterior 28F pleuraltube is placed on each side.

When implantation occurs on CPB, as aforementioned, bilateral pneumonectomies are performed, posterior thoracotomy sutures and pleural drains are placed, and both lungs are implanted prior to reperfusion. The first lung that is implanted is packed in ice slush during implantation of the second lung. Methylprednisolone (1 g) and mannitol (50 g) are administrated prior to reperfusion. While the lungs are ventilated with room air, gradual reperfusion is initiated starting at 5 to 10 mmHg mean PA pressure and increasing by 5 mmHg every 5 minutes until normal systemic pressures are achieved. Reperfusion of the lungs with oxygenated hypocarbic blood may be especially advantageous to maximize pulmonary vascular recruitment and parenchymal recovery.

In patients undergoing double-lung transplants without CPB, once appropriate hemodynamics and oxygenation are confirmed after reperfusion of the first transplanted lung, the remaining native lung is removed. Implantation proceeds in a fashion similar to that of the first lung. The performance of bilateral dissection and mobilization...
performed to (1) assess the adequacy of the pulmonary perfusion solutions, the addition of the initial pressure and flow through initially greatly reduces the duration in volumes between when the pleural tubes pleural space is substantially larger than posterior pleural space. For bilateral transplant, the entire systemic blood flow passes which the entire systemic blood flow passes through the pleural tubes placed in the anterior and posterior pleural space. For bilateral transplants performed using a clamshell incision, the anterior aspect of the clamshell opening is approximated with three sets of #5 wires, one simple set in the midline of the sternum, and one set of figure-of-eight on each side of the midline with the lateral aspect placed lateral to the mammary pedicle. The remainder of the clamshell opening is reapproximated with a series of #1 Maxon sutures in a figure-of-eight fashion. As described earlier, the Maxon sutures on the lateral most aspect of the clamshell opening have been placed while the native lungs were either deflated or removed. If not already done, a Blake drain into each of the axillary space is placed. The pectoral fascial layer, the subcutaneous layer, the subdermal layer, and the skin are then approximated.

Chest tubes are placed to suction except in circumstances in which the recipient pleural space is substantially larger than the donor lung size. In these situations, chest tubes are left to water seal to prevent overdistention of the lung allograft, stretch injury, and severe PGD. This situation can be identified by marked differences in tidal volumes between when the pleural tubes are on or off suction.

After dressings are applied, the double-lumen endotracheal tube is removed and a large, single-lumen endotracheal tube is placed. Fiberoptic bronchoscopy is performed to (1) assess the adequacy of the anastomosis, (2) clear secretions, (3) assess for the development of PGD as manifested by severe pulmonary edema, and (4) evaluate for torsion or malrotation of the allograft manifest by abnormal, crescent-shaped distal airways.

**Primary Graft Dysfunction**

Through the use of extracelluar-based pulmonary perfusion solutions, the addition of retrograde pulmonary perfusion to the preservation regimen, minimal oxygen exposure at the time of reperfusion, control of the initial pressure and flow through the lung allograft, and the use of oxygen free-radical scavengers, the incidence of severe PGD has decreased from 15% to 25% to as little as 5%. However, development of severe allograft dysfunction as demonstrated by marked hypoxia, pulmonary edema, elevated PA pressures, and poor compliance requires immediate investigation for reversible causes. Most importantly anastomotic or mechanical causes, especially venous outflow problems, need to be identified and corrected immediately. With respect to venous outflow obstruction, if correction is delayed for more than 4 to 6 hours it is unlikely that any reasonable allograft recovery will be achieved. Interruption of the anastomoses includes visual inspection to assess for torsion or kinking, TEE to assess for turbulent or absent pulmonary vein flow as well as left atrial anastomotic quality, the presence of intraluminal clot, and direct measurement of pressures across the anastomosis. Cardiac etiologies usually can be identified by TEE including left-sided valvular abnormalities, left ventricular failure, intracardiac shunts, and tamponade. We routinely obtain a quantitative perfusion scan within the first few hours after the transplant with lobar or greater perfusion defects necessitating further assessment, usually by operative exploration. Asymmetric pulmonary edema or crescent-shaped airways on bronchoscopic evaluation may be indicative of mechanical problems. PGD can be caused by humoral lung injury from circulating antidonor antibodies. These antibodies are identified by donor–recipient crossmatching. Treatment of donor-specific antibodies is multimodal, including plasmapheresis, column absorption, intravenous immunoglobulin, and anti-B cell therapies such as anti-CD20 (rituximab).

Severe PGD causes significantly contribute to the majority of early post-transplant deaths. Unless reversible causes could be identified, treatment has been supportive with optimization of ventilator parameters, inotropic support, and nitric oxide. We have shifted to a strategy of early institution of venovenous (V-V) ECMO when recipients develop severe pulmonary edema or require FIO2 > 60%. V-V cannulation is typically instituted via the right femoral vein with a venous catheter (Bio-Medics) and the left internal jugular vein with a pediatric arterial cannula (Medtronic, Minneapolis, MN). Cannulae are placed percutaneously using a modified Seldinger technique over a guidewire following serial dilatations. The circuit consists of a hyaluron-based heparin-coated 3/8 inch tubing with a Quadrox D polymethylpentene (PMP) oxygenator and Jostra Rotaflow pump (MAQUET Cardio-pulmonary AG, Hirrlingen, Germany). The optimal placement of circuit inflow and outflow ports are determined by the level of recirculation noted in the system. ECMO flows are approximately 2.5 to 3.5 L/minute with a sweep gas flow adjusted to maintain the pCO2 close to 30 mmHg so as to maximize pulmonary vasodilation. During V-V ECMO support, a protective ventilatory strategy is used including low oxygen and low pressure ventilation. Weaning from V-V ECMO involves discontinuing membrane gas flow and increasing ventilatory parameters as needed. No increase in anticoagulation is required for V-V ECMO weaning. Using this strategy, patients are weaned from ECMO, usually after 3 to 5 days of support, because pulmonary vascular resistance decreases following institution of ECMO and pulmonary capillary leak usually resolves more quickly (often within 24 hours). The 30-day survival in patients requiring V-V ECMO at our institution is approximately 90%.

**Principles of Postoperative Care**

While an extensive discussion of postoperative care is beyond the scope of this text, a few principles are important. Optimal pain control, especially for bilateral transplant recipients, is achieved with epidural analgesia. Most patients with good allograft function should be extubated within 24 hours of the transplant and can be discharged from the hospital within 10 to 14 days of the transplant. While the optimal immunosuppressant regimen is not known, most programs use a triple-drug regimen including a calcineurin inhibitor (cyclosporin or tacrolimus), an antiproliferative agent (Imuran or mycophenolate mofetil), and corticosteroids. Induction therapy using either an anti-CD25 agent (basiliximab or daclizumab), or an immune cell depleting strategy such as polyclonal anti-T cell agents (thymoglobulin, ATGAM), or most recently anti-CD52 (Campath) are used in approximately 50% of lung transplant recipients. While acute rejection occurs commonly after lung transplant with 40% to 60% of patients having at least one episode of rejection in the first 6 months, it is an uncommon cause of early mortality. Mortality early after lung transplant is most commonly secondary to poor allograft function, infection, and neurologic and cardiac events. The immunosuppression and infection prophylaxis protocols used by the Duke Lung Transplant Program are outlined in Tables 23.1 and 23.2.

A factor that appears to be related to lung allograft injury that has been underestimated in its prevalence is aspiration injury. In addition to the infrequent, classic aspiration pneumonitis, repetitive injury
secondary to microaspiration appears to occur commonly. Factors that increase the risk of aspiration include the high prevalence of gastroesophageal reflux in patients with end-stage lung disease, particularly in those patients with IPF and CF. Gastroesophageal reflux is even more common and of greater severity following lung transplant because of issues related to both the medication regimen and vagal nerve injury. Vagal nerve injury also contributes to gastroparesis that can exacerbate the amount of esophageal reflux. Additionally, abnormal oropharyngeal swallowing appears to occur in many patients often as a result of left recurrent laryngeal nerve injury. We routinely assess all patients for gastroesophageal reflux both before and soon after lung transplant and we perform an endoscopic swallowing evaluation after transplant prior to initiating oral intake. In patients with severe gastroesophageal reflux, surgical fundoplication is performed early after the lung transplant, often during the posttransplant stay. Patients who fail their swallowing evaluation receive nutritional support via enteric tube placed distal to the ligament of Treitz until their oropharyngeal function normalizes. In patients with vocal cord paralysis or paraparesis, vocal cord medialization is performed. Bronchoscopic examination is performed frequently in the early posttransplant period. It is carried out both to observe the airway anastomoses and to obtain transbronchial biopsies to investigate new infiltrates, fevers, or allograft dysfunction as manifested by worsening oxygenation, hypercapnia, and decreased spirometric values. While pulmonary embolism is uncommon after lung transplant, the potentially devastating consequence of pulmonary infarction in the face of the known lack of bronchial artery perfusion that characterizes a newly implanted lung allograft requires a high degree of vigilance with respect to diagnosis and treatment. Surgical embolectomy of large pulmonary emboli occasionally may be indicated.

**CONCLUSIONS**

Tremendous progress has occurred in lung transplantation over the last two decades. One-year patient and allograft survival now compares favorably to those of liver and cardiac transplantation. As with all solid-organ transplantations, the shortage of available donor organs and the development of chronic allograft injury are the primary limitations to a greater applicability to the treatment of end-stage lung diseases. While the potential development of expanded organ sources through xenotransplantation, lung organogenesis, and ex vivo perfusion systems will greatly impact the future numbers of lung transplants performed, there appears to be a substantial number of suitable organs, especially lungs, that could become available if the majority of donors were evaluated appropriately. With a better understanding of the causes of lung allograft injury and ongoing work toward developing immunologic tolerance, improved long-term outcome is achievable.

**Treatment of Rejection**

**Minimal or mild rejection episodes (ISHLT Grade 1 or 2):** Solu-Medrol 500 mg IV daily × 3 doses followed by oral prednisone taper starting at 60 mg and decreasing by 5 mg/d until original dose is reached.

**Moderate (ISHLT Grade 3) or steroid-resistant rejection:** RATG (thymoglobulin) 1.5 mg/kg for three doses. Premedicate 30 min prior to each dose with Solu-Medrol 40 mg IV, diphenhydramine 50 mg IV, and acetaminophen 650 mg PO.
Table 23.2 Duke University Infection Prophylaxis

**Bacterial**

**Standard Regimen**

Ceftazidime: 2 g IV preoperatively on induction per anesthesia, then 1 g IV every 8 h for 7–10 d or until invasive lines are out. (Adjust doses for renal insufficiency.)

Vancomycin: 1 g IV preoperatively on induction per anesthesia, then 1 g IV every 12 h for 7–10 d or until invasive lines are out. (Adjust doses for renal insufficiency.)

**CMV\(^b\)/HSV\(^c\)/EBV\(^d\)**

**Donor negative/recipient negative**

Leukoreduced red blood cell transfusions only. If HSV negative, no prophylaxis; if HSV positive, acyclovir 200 mg PO every 8 h for 12 wk.

**Donor positive/recipient negative**

Ganciclovir 5 mg/kg IV every 12 h for 4 wk, followed by ganciclovir 5 mg/kg IV daily for 10 wk, followed by Valcyte 450 mg PO daily, indefinitely.

**Donor negative/recipient positive OR donor positive/recipient positive**

Ganciclovir 5 mg/kg IV every 12 h for 2 wk followed by ganciclovir 5 mg/kg IV daily for 2 wk.

**Pneumocystis carinii**

Septra DS 1 tablet PO every Monday, Wednesday, and Friday starting 1 wk postoperatively and continuing indefinitely.

If sulfa allergy, Dapsone 50 mg PO daily or aerosolized pentamidine 300 mg every mo continuing indefinitely.

**Fungal**

Nystatin suspension 5 ml swish and swallow 4 times/d for oral candida prophylaxis. Continue for 6 mo.

Inhaled amphotericin B 50 mg daily for 4 d, then weekly while hospitalized immediately post-transplant (dose to be reduced to 25 mg once patient is extubated).

**Toxoplasmosis gondii (use only for donor positive/recipient negative)**

Septra DS 1 tablet daily starting 1 wk postoperatively (also covers PCP prophylaxis).

If sulfa allergy, pyrimethamine (Daraprim) 50 mg PO daily and folinic acid (leucovorin) 10 mg PO daily for 6 mo (use in addition to pentamidine for PCP prophylaxis).

---

*The standard regimen should be amended as indicated to include (1) coverage for any other known preoperative pathogens in the recipient. This is particularly indicated for recipients with cystic fibrosis, bronchiectasis, and other septic lung diseases; (2) coverage for any additional organisms identified from donor bronchial washings. If OR and first BAL cultures are negative at 72 h postoperatively, change IV antibiotics to Levaquin or Moxifloxacin 500 mg PO daily for 7 d.

*Use Valcyte 450 mg PO BID for the duration of the above protocols as long as the patient is tolerating oral intake, normal GI function, WBC >5,000, and creatinine <1.5.

*For all EBV-negative recipients: Ganciclovir 5 mg/kg IV every 12 h for 4 wk, followed by Valcyte 450 mg PO daily, indefinitely.

*Patients receiving RATG (thymoglobulin) therapy treated with Ganciclovir at a dose of 5 mg/kg IV every 12 h (or appropriate treatment dose based on renal function) for 3 wk for CMV prophylaxis.

*If patient intolerant of daily pyrimethamine, use Dapsone 50 mg daily with pyrimethamine 50 mg weekly and folinic acid 10 mg weekly.
Lung transplantation is now a well-accepted therapeutic option for many patients with end-stage lung disease, yet the 5-year survival is less than 50%. The major issue relating to long-term survival continues to be the problem of obliterative bronchiolitis. Efforts have been made to improve overall survival by changing donor lung allocation methodology from simply time on the waiting list to one where patients are given a lung allocation score (LAS) that directs donor lungs to those patients who are most likely to derive the maximum benefit. The LAS is calculated from a series of formulas that take into account the statistical probability of a patient’s survival in the next year without a transplant, how long that survival would be, the probability of survival following a transplant, and the projected length of survival posttransplant. In addition to this revised allocation methodology, marginal donor lungs are now being more frequently utilized. The development of ex vivo lung perfusion systems that allow for improving some of these marginal lungs is also likely to add to the donor pool. The lungs are the first organ to deteriorate in the brain-dead patient and thus are usable for transplant far less than any of the other organs.

The issue of single lung versus bilateral sequential lung transplants remains somewhat controversial though the long-term survival when both lungs are transplanted is superior. Many centers now use single-lung transplants very sparingly despite the fact that overall less recipients benefit.

I was particularly intrigued by the Duke group’s low threshold for using venovenous ECMO for patients who are having oxygenation problems and specifically the outstanding success that they have experienced in this challenging group. In addition, the recognition of the role that so-called microaspiration plays in allograft dysfunction has been woefully underestimated and was initially brought to our attention by Dr. Davis and his colleagues at Duke. It has long been thought that there was an element of swallowing dysfunction following pneumonectomy; so it is not surprising that many patients post lung transplant have significant swallowing issues as well as reflux.

The issue of primary graft dysfunction continues to plague lung transplantation and has implications for long-term survival. Better lung preservation regimens have reduced the incidence but certainly not eliminated it.

LRK
Thoracic outlet syndrome (TOS) is a group of conditions caused by compression of the neurovascular structures that serve the upper extremity as they pass through the lower part of the neck, behind the clavicle, and over the first rib (Fig. 24.1). The clinical presentation of TOS depends on the specific structures compressed, giving rise to three distinct conditions: (1) Neurogenic TOS (NTOS), caused by compression and irritation of the brachial plexus nerves; (2) Venous TOS (VTOS), caused by compression of the subclavian vein leading to venous thrombosis; and (3) Arterial TOS (ATOS), caused by compression of the subclavian artery, leading to degenerative changes and thromboembolism. Although all three types of TOS are considered to be relatively uncommon, clinical recognition and appropriate treatment of these conditions is crucial to prevent disability in young active individuals.

NEUROGENIC THORACIC OUTLET SYNDROME

NTOS is the most frequent form of thoracic outlet compression, occurring in 85% to 90% of patients. It is due to compression and irritation of the brachial plexus nerve roots within the scalene triangle or underneath the pectoralis minor muscle tendon in the subcoracoid space. NTOS is considered to be caused by a combination of variations in anatomy (such as anomalous scalene musculature, aberrant fibrofascial bands, or cervical ribs) and previous neck or upper extremity injury that has resulted in scalene or pectoralis minor muscle spasm, fibrosis, and other pathologic changes. These muscular alterations, in turn, lead to compression and irritation of the adjacent brachial plexus nerves.

Brachial plexus nerve root compression can result in diverse symptoms that usually include pain, numbness, and tingling (paresthesia) in the neck, shoulder, arm, and hand. The intensity of these symptoms can vary, depending on levels of upper extremity activity, and are typically exacerbated with position, especially arm abduction and elevation. Although many patients with NTOS have relatively mild symptoms, with a slow gradual progression interspersed by occasional exacerbations, some exhibit a steady progression in the severity of symptoms leading to increasing and significant disability.

The diagnosis of NTOS is based on clinical evaluation, with supplemental testing procedures to exclude alternative or coexisting conditions (Table 24.1). On physical examination there is usually well-localized tenderness to palpation over the supraclavicular scalene triangle and/or the infraclavicular subcoracoid space, usually associated with reproduction of upper extremity symptoms. Most patients with NTOS report a rapid reproduction of upper extremity symptoms with provocative positional maneuvers, such as the upper limb tension test (ULTT) or the 3-minute elevated arm stress test (3-min EAST). Physical examination of patients suspected to have NTOS should also exclude any evidence of arterial or venous compromise to the upper extremity. Plain anteroposterior chest radiographs are useful to determine the presence or absence of a cervical rib, but other imaging studies of the brachial plexus are not specifically helpful in diagnosis. Conventional electrophysiologic testing (electromyography and nerve conduction studies) is often performed to exclude peripheral nerve compression disorders or cervical radiculopathy, but these tests are usually negative or nonspecific in NTOS. Image-guided anterior scalene muscle and/or pectoralis minor muscle blocks with a short-acting local anesthetic can provide support for the clinical diagnosis of NTOS, as well as help predict the reversibility of symptoms with treatment.

Initial treatment for NTOS is based on physical therapy to relieve muscle spasm, improve postural disturbances, enhance functional limb mobility, strengthen associated shoulder girdle musculature, and diminish repetitive strain exposure in the workplace. Incorrect approaches to physical therapy can result in worsening of symptoms and premature failure of conservative management. In most patients with mild NTOS or symptoms of short duration, significant improvement is observed within the initial 4 to 6 weeks and therapy is then continued on an "as needed" basis. Because NTOS is often a chronic condition subject to occasional “flare-ups” of acute symptoms (often related to overuse activities or new injury), the patient should continue regular physical therapy exercises during long-term follow-up.

Surgical treatment is recommended for patients with NTOS when the clinical diagnosis is sound, the patient has substantial disability (symptoms interfere with daily activities and/or work), and there has been an insufficient response to an appropriate course of physical therapy. Surgical treatment may also be recommended in selected patients with persistent or recurrent symptoms of NTOS following a previous operation, when there has been no response to appropriate conservative measures. Thoracic outlet decompression for NTOS may be accomplished by transaxillary operations focused on first rib resection, or by supraclavicular operations that include scalenectomy, first rib resection, and brachial plexus neurolysis. For patients with symptoms of NTOS referable to the subcoracoid space, surgical decompression may include pectoralis minor tenotomy as an addition to transaxillary or supraclavicular thoracic outlet decompression, or as an isolated procedure when this site is the dominant location of nerve compression symptoms.

VENOUS TOS

VTOS is characterized by subclavian vein compression between the clavicle, subclavian muscle, costoclavicular ligament, and first rib. The pathogenesis of VTOS involves repetitive extrinsic compression of the subclavian vein during activities involving arm...
elevation or exertion, leading in time to chronic focal venous injury and progressive fibrous stenosis due to scar tissue formation and contraction around the outside of the vein, as well as fibrosis and wall thickening within the wall of the vein itself.

The initial phase of VTOS is usually asymptomatic, due to simultaneous expansion of collateral veins passing around the narrowed subclavian vein, but stagnant blood within the damaged segment of the subclavian vein eventually leads to thrombotic occlusion. Growth and peripheral extension of this clot into the axillary vein can further obstruct critical collateral veins, resulting in the acute clinical presentation characterized as axillary-subclavian vein “effort thrombosis” (Paget-Schroetter syndrome). Patients with subclavian vein effort thrombosis typically present with abrupt spontaneous swelling of the entire arm, often with cyanotic (bluish) discoloration, heaviness, and aching pain. Unlike more common forms of deep venous thrombosis (DVT), VTOS tends to occur in young, active, and otherwise healthy individuals, with no underlying blood clotting disorder.

Pulmonary embolism from clot within the proximal subclavian vein may also occur, particularly with motion of the arm, but this is infrequent compared to DVT in the lower extremities.

The stereotypical clinical presentation of axillary-subclavian vein effort thrombosis is usually sufficient to establish the diagnosis of VTOS. Although venous duplex studies of the upper extremity may be used to confirm the presence of DVT, duplex imaging of the subclavian vein is inaccurate and cannot be used to exclude the diagnosis. In contrast, imaging studies such as magnetic resonance angiography or catheter-based venography provide more definitive information on the location and extent of axillary-subclavian vein thrombosis, and can be performed with the arms in elevation when there is incomplete subclavian vein obstruction. The distinct advantage of using catheter-based venography as the initial diagnostic step is that this can be followed immediately by thrombolytic therapy, which is often considered the first step in treatment. It is important to note that while blood coagulation testing is often performed in patients with upper extremity DVT, these tests are usually negative in those with VTOS and add little to the initial diagnosis or management.

Exclusion of other conditions typically includes nonspecific or negative findings on physical examination (Spurling’s test, axial compression test, Tinel’s sign over the carpal tunnel or cubital tunnel, and Phalen’s test), imaging studies (MRI of cervical spine and shoulder), and conventional electrophysiologic tests (upper extremity electromyography and nerve conduction studies).

Following the diagnosis of subclavian vein effort thrombosis by contrast venography, catheter-based thrombolytic therapy is recommended to reduce the amount of thrombus within the axillary and subclavian veins. In recent years this has been facilitated by pharmacomechanical approaches, where thrombolysis can usually be accomplished in a single setting. In most cases this results in a rapid reduction in the burden and extent of thrombus, and reveals a residual high-grade focal stenosis or occlusion of the subclavian vein at the level of the first rib. Balloon angioplasty may be used to reduce the degree of residual stenosis, but this is often unsuccessful at overcoming extrinsic bony compression or scar tissue within the wall of the vein. Over the past decade it has also become increasingly clear that placement of stents within the subclavian vein frequently leads to poor outcomes and should therefore be avoided. Following catheter-based venography and thrombolysis, patients with VTOS are maintained on therapeutic anticoagulation while considering further treatment options.

One option for treatment of VTOS consists of conservative treatment with chronic anticoagulation and long-term restrictions in arm activity, in the hope that recurrent venous thrombosis will not occur and that increased collateral development will eventually compensate for any residual axillary-subclavian vein obstruction. Even with satisfactory anticoagulation this approach is associated with recurrent thrombosis or chronic venous congestion in 50% to 70% of patients, and there is no information available on the optimal duration of anticoagulation for this condition. Lifelong anticoagulation and aggravation of symptoms during active use of the arm may also require considerable limitations, which are usually unacceptable for young active patients.

Surgical treatment is recommended within several weeks for almost all patients with VTOS, both to avoid long-term disability from venous obstruction and the need for long-term anticoagulation, and to permit a prompt return to normal activities. Surgical treatment is also recommended in patients with previous axillary-subclavian vein thrombosis that have remained symptomatic despite anticoagulation and restricted activity, as well as for asymptomatic individuals in whom long-term anticoagulation and restrictions on upper extremity activity are undesirable.

**ARTERIAL TOS**

ATOS is caused by subclavian artery compression within the scalene triangle, leading to the development of fixed subclavian artery stenosis, occlusion, or poststenotic subclavian artery aneurysms. ATOS almost always occurs in association with a congenital cervical rib or other bony anomaly. The development of subclavian artery surface ulceration or aneurysmal dilatation is often accompanied by mural thrombus formation, which frequently leads to distal thromboembolism with hand and/or digital ischemia. A second form of ATOS is observed in overhead throwing athletes, associated with occlusive or aneurysmal lesions of the distal axillary artery. These lesions are caused by repetitive trauma from hyperextension during the throwing motion, in which the axillary artery is compressed by forward motion of the head of the humerus. The thromboembolic complications of these lesions are similar to those of ATOS caused by subclavian artery lesions at the level of the first rib.

Patients with ATOS often present with acute thromboembolism in the upper extremity, characterized by the sudden onset of hand pain and weakness, numbness and tingling, and cold and pale fingers. Patients with more longstanding ischemia may present with chronic arm fatigue or claudication, nonhealing wounds, or ulcerations in the fingers. Subclavian artery occlusions or aneurysms may also be asymptomatic, with occlusions identified by a significant blood pressure differential between arms and aneurysms presenting as a nontender pulsatile mass in the lateral neck.

ATOS is usually readily suspected by clinical findings. The diagnosis may be confirmed by noninvasive vascular laboratory studies, such as duplex imaging and segmental arterial waveform analysis. Plain radiographs are important to determine if a cervical rib or first rib anomaly is present. Positional angiography (with either contrast-enhanced magnetic resonance imaging, computed tomography, or catheter-based arteriography) is typically performed to determine the presence or absence of a subclavian artery aneurysm. Similar imaging studies are performed in patients that have presented with upper extremity arterial thromboembolism to determine if a proximal source of embolism exists in the subclavian or axillary artery.

Immediate anticoagulation and urgent surgical treatment is recommended in patients with ATOS and acute upper extremity ischemia due to thromboembolism. Initial treatment may involve brachial artery exposure and thromboembolectomy to improve the distal circulation in the hand, with or without intraarterial infusion of thrombolytic and vasodilator agents. Treatment of the distal circulation should be immediately followed by thorough arteriographic assessment of the axillary and subclavian arteries, to establish a proximal source of thromboembolism, followed by thoracic outlet decompression and arterial reconstruction. For patients with stable distal circulation found to have ATOS, direct elective surgical treatment is recommended. Therapeutic anticoagulation and antiplatelet therapy are continued in all patients from the time of diagnosis until definitive surgical treatment.

**SURGICAL PROCEDURES**

**Transaxillary Decompression**

The patient is positioned supine or in lateral position under general anesthesia, with the back of the table raised about 30 degrees. The affected side is elevated with a small towel pack placed behind the shoulder. The arm is circumferentially prepped and wrapped in stockinette, with a sterile field that includes the neck, upper chest, and posterior shoulder to the scapula. Some surgeons prefer to place the arm on a table or fixed to a crossbar, but the same positioning can be accomplished by a reliable, flexible, and sturdy assistant.

A transverse skin incision is made at the lower border of the axillary hairline and carried through the subcutaneous tissues directly to the chest wall. A tissue plane extending to the apex of the axilla is established by blunt dissection near the chest wall and the long thoracic, thoracodorsal, and second intercostal brachial nerves are identified to avoid direct injury. Specific attention is directed to avoid excessive elevation of the arm, to prevent stretch injury to the intercostobrachial cutaneous nerve (which can result in troublesome postoperative pain and numbness along the medial aspect of the arm). The first rib is identified by palpation along the chest wall, and using a Deaver retractor to gently lift away the subcutaneous tissues and axillary contents, the rib is exposed in the upper aspect of the wound. The arm should be carefully elevated to facilitate this exposure and the operating surgeon should use a directed fiberoptic headlight to illuminate the operative field. Some surgeons have advocated the use of video-assisted exposure, using an endoscopic camera, as an...
adjacent to visualization. Throughout the transaxillary procedure the operating surgeon must be continually aware of the position of the assistants and retractors with respect to the brachial plexus nerve roots and subclavian blood vessels, and attention must be given to avoid traction on the long thoracic nerve that exits the plane between the middle and posterior scalene muscles before coursing over the first rib to the serratus anterior muscle. A staged approach with periodic reinspection of the retractors and relief for the assistants is recommended.

Following exposure of the first rib, the subclavian vein and artery are identified along with the intervening anterior scalene muscle. These structures are carefully dissected to the point that the anterior scalene tendon can be encircled with a right-angle clamp, just above its insertion on the first rib (typically palpable as a slight bony prominence). While avoiding the phrenic nerve to expose several centimeters of the anterior scalene muscle superior to the first rib, the muscle is divided with a scissors. Because reattachment of the divided anterior scalene muscle is one of the principal causes of recurrent NTOS following transaxillary first rib resection, it is important to resect a portion of the scalene muscle rather than simply detach it from the bone.

Soft tissue attachments to the inferior and medial borders of the first rib are progressively divided by scissor dissection, starting medial to the subclavian vein (the subclavus muscle tendon and costoclavicular ligament). A periosteal elevator is then used along the inferior border of the rib to divide the intercostal muscle, and the parietal pleura is pushed away from the deep aspect of the rib by blunt dissection. At a level posterior to the brachial plexus nerve roots, the middle scalene muscle is similarly detached from the superior surface of the rib. Injury to the long thoracic nerve is avoided by keeping the periosteal elevator directly upon the rib during scalene muscle detachment. Once the posterior aspect of the first rib is exposed and the T1 nerve root is in full view and protected from injury, a C-shaped rib shears is carefully placed upon the neck of the rib and applied. The lateral portion of the divided rib is pulled downward and its anterior aspect is divided in a similar manner at the costochondral junction, immediately medial to the subclavian vein, and the rib is fully detached and removed. A Kerrison bone rongeur is then used to smooth the remaining ends of the bone beyond the level of the neurovascular structures. Once the first rib has been removed, the surgeon should identify any additional soft tissue bands that might cross the brachial plexus nerve roots and carefully divide these structures. After hemostasis is achieved, the wound is irrigated and a Valsalva maneuver is initiated to detect any rents in the pleura. A small closed-suction drain is placed through a separate wound (to be maintained on suction for 24 to 48 hours) and the incision is closed in two layers.

Supraclavicular Decompression

The patient is positioned supine under general anesthesia with the head of the bed elevated 30 degrees. The neck is turned to the opposite side and a small inflatable pillow is placed between the shoulders. The neck, upper chest, and affected upper extremity are prepped into the field, with the arm wrapped in stockinette and held comfortably across the abdomen (Fig. 24.2). A transverse incision is made parallel to and just above the clavicle, beginning at the lateral border of the sternocleidomastoid muscle and extending to the anterior border of the trapezius. The platysma layer is divided and the sternocleidomastoid muscle is retracted medially. Beginning at the lateral edge of the internal jugular vein, the scalene fat pad is detached and mobilized with ligation of small blood vessels and lymphatic tissues. A short segment of the omohyoid muscle is resected and the scalene fat pad is further mobilized from its inferior and superior attachments.

Following lateral mobilization of the scalene fat pad by gentle blunt dissection, the underlying anterior scalene muscle and phrenic nerve are exposed, along with the brachial plexus. The middle scalene muscle is exposed where it attaches to the upper surface of the first rib behind the brachial plexus, and the long thoracic nerve is identified emerging from the body of the middle scalene muscle to pass across the lateral first rib. The scalene fat pad is then held in position with several retraction sutures and the exposure is maintained with Henley self-retaining retractor (using the third arm to hold the edge of the sternocleidomastoid muscle). The resulting exposure represents the first critical view to be obtained during supraclavicular decompression (Fig. 24.3).

To resect the anterior scalene muscle, the brachial plexus and subclavian artery are separated from the lower lateral edge of the muscle until a fingertip can be easily passed behind the muscle just above the first rib. The neurovascular structures are thereby displaced posteriorly, and blunt finger dissection is continued behind the anterior scalene to its medial border. Once the insertion of the anterior scalene muscle onto the first rib has been isolated under direct vision, it is sharply divided with scissors (Fig. 24.4).

The lower end of the divided anterior scalene muscle is elevated and its attachments to the subclavian artery and the thickened extrapleural fascia are sharply divided. The muscle is lifted further after passing it underneath the medial side of the phrenic nerve, and its posterior attachments are divided with direct visualization and protection of the upper brachial plexus nerve roots. The anterior scalene muscle is detached from its origin on the transverse process of the cervical spine and the entire muscle is removed (Fig. 24.4). Any scalene minimus muscle fibers identified during resection of the anterior scalene muscle are resected, as are any anomalous fibrofascial bands, to ensure thorough decompression and full mobility of the brachial plexus nerve roots.

The brachial plexus nerve roots are next separated from the front edge of the middle scalene muscle to the level of the first rib and a small malleable retractor is placed between the muscle and the nerves. With medial retraction of the brachial plexus, each nerve root from C5 to T1 is sequentially identified. A second malleable retractor is placed lateral to the middle scalene muscle and first rib to permit the long thoracic nerve to be displaced posteriorly, and the attachment of the middle scalene muscle along the top of the lateral first rib is exposed and divided from the rib using the electrocautery (Fig. 24.5). The middle scalene muscle is further detached along the top of the posterior first rib using

---

Fig. 24.2. Positioning and incision for supraclavicular thoracic outlet decompression. Patient position and planned incision for supraclavicular thoracic outlet decompression. The skin incision is made just above and parallel to the clavicle, extending from the lateral border of the sternocleidomastoid muscle to the anterior border of the trapezius muscle. With permission from Fischer JE, et al., eds. Mastery of Surgery, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2012.

The remaining intercostal muscle and fascial attachments to the first rib are divided anteriorly to the level of the scalene tubercle. While elevating the clavicle with a small Richardson retractor, the rib is displaced inferiorly to open the anterior costoclavicular space and the rib shears are placed around the anterior first rib immediately medial to the scalene tubercle. The proximal first rib is then divided and the specimen removed from the operative field (Fig. 24.7). The remaining anterior end of the first rib is remodeled to a smooth surface with a Kerrison rongeur and sealed with bone wax.

When there is a cervical rib present, these anomalous structures are found to arise within the tissue plane of the middle scalene muscle, posterior to the brachial plexus and subclavian artery. Incomplete cervical ribs typically have a ligamentous extension to the first rib, whereas complete cervical ribs attach to the lateral first rib in the form of a true joint. The posterior portion of a cervical rib is thereby readily encountered during dissection of the middle scalene muscle and divided in a manner similar that of the posterior first rib. The anterior attachment of the cervical rib is then divided and the bone is removed. When there is a true joint formed between a complete cervical rib and the first rib, the anterior portion of the cervical rib is left attached while the first rib resection is completed, and the two are removed together as a single specimen.

The last step of supraclavicular decompression is to fully mobilize each of the nerve roots of the brachial plexus and to remove any adherent fibrous scar tissue that might impair mobility (external neurolysis). Each of the contributing nerve roots (C5-T1) is meticulously dissected free.
Fig. 24.4. Anterior scalene muscle. The lower part of the anterior scalene muscle is circumferentially mobilized from the underlying subclavian artery and roots of the brachial plexus, to isolate the muscle insertion on the top of the first rib (A). With the subclavian artery and brachial plexus protected by a finger, the insertion of the anterior scalene muscle is sharply divided from the top of the first rib (B). The anterior scalene muscle is dissected free of underlying structures to the level of its origin on the transverse process of the cervical vertebra (C). After passing the muscle underneath and to the medial side of the phrenic nerve, the muscle origin is safely divided. With permission from Fischer JE, et al., eds. Mastery of Surgery, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2012.
Fig. 24.5. Middle scalene muscle insertion. The insertion of the middle scalene muscle on the first rib is exposed by gentle medial retraction of the brachial plexus and posterolateral retraction of the long thoracic nerve (which is found emerging from the body of the middle scalene muscle) (A). With this exposure the insertion of the middle scalene muscle can be safely divided from the top of the first rib with a periosteal elevator or cautery, and resected along the bone to reach the posterior portion of the first rib (B). With permission from Fischer JE, et al., eds. Mastery of Surgery, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2012.

of any perineural fibrous tissue. This aspect of the operation is not considered to be complete until each nerve root has been completely cleared throughout its course within the operative field. Upon completion of supraclavicular decompression, the apex of the pleural membrane is opened and a closed-suction drain is placed into the supraclavicular field, where it is positioned behind the brachial plexus with its tip lying in the upper posterior pleural space. Two multihole catheters for postoperative infusion of local anesthetic are placed within the wound, adjacent to the brachial plexus and within the bed of the resected first rib. A bioresorbable (polylactide) film is wrapped around the brachial plexus to suppress development of postoperative perineural fibrosis, and the scalene fat pad is reattached to lie over the brachial plexus. The edges of the platysma muscle are reaproximated and the skin is closed.

**Pectoralis Minor Tenotomy**

With the patient positioned supine under general anesthesia, a short vertical infraclavicular incision is made just below the coracoid process, extending to the deltopectoral groove. The plane of dissection is kept medial to the cephalic vein as the deltoid and pectoralis major muscles are separated. The lateral edge of the pectoralis major muscle is lifted, the underlying fascia is exposed, and the space between the pectoralis major and minor muscles is developed by blunt dissection. The pectoralis minor muscle tendon is exposed and encircled near its insertion on the coracoid process, taking care to protect the underlying neurovascular bundle. The tendon is then divided with electrocautery under direct vision, within 1 to 2 centimeters of the coracoid process, allowing the divided muscle to retract inferiorly, and the edge of the divided muscle is oversewn to ensure hemostasis. The remaining clavipectoral fascia is opened to the level of the clavicle, but no further dissection of the brachial plexus or axillary vessels is performed.

**Management of Venous Thoracic Outlet Syndrome (Paraclavicular Decompression)**

In the surgical treatment of VTOS, we prefer to utilize an anterior approach that permits complete resection of the first rib along with direct axillary-subclavian vein reconstruction in the same setting. This begins with supraclavicular decompression as described above for NTOS, with the exception that the anterior portion of the first rib is not yet divided. Following the supraclavicular portion of the procedure, a second transverse skin incision is made several centimeters below the medial clavicle. By dissecting between the
upper and middle portions of the pectoralis major muscle, the cartilaginous portion of the anterior first rib is identified. This exposure is facilitated by applying downward fingertip pressure on the divided posterior segment of the first rib through the supraclavicular incision, which places the attachments between the medial first rib and clavicle under tension. Soft tissue attachments to the superior edge of the first rib are then dissected from exposure through the infraclavicular incision, and the subclavius muscle tendon, the costoclavicular ligament, and the muscles of the first intercostal space are all divided under direct vision. The anterior portion of the first rib is divided adjacent to the sternum and the entire first rib is then removed as a single specimen.

Through the lateral portion of the infraclavicular incision, the axillary vein is identified underneath the clavicle. The vein is traced and carefully separated from the subclavius muscle, and the subclavius muscle and its tendon are completely resected. Through the supraclavicular incision, the subclavian vein is exposed medially toward its junction with the internal jugular and innominate veins, and cleared of any external fibrous tissue (circumferential external venolysis). The internal jugular vein is circumferentially exposed for several centimeters above its junction with the subclavian vein, and the innominate vein is exposed for several centimeters into the upper mediastinum.

In many patients with VTOS, external venolysis is sufficient to allow reexpansion of the subclavian vein to a normal caliber. If the underlying vein is also soft to palpation and easily compressible, it is likely that no further venous reconstruction will be necessary. Additional subclavian vein reconstruction is performed when there is residual vein wall thickening despite external venolysis or residual subclavian vein stenosis by intraoperative venography. Following infusion of low molecular weight Dextran and administration of intravenous heparin, the axillary-subclavian vein, internal jugular vein, and the upper portion of the innominate vein are all controlled with clamps. The subclavian vein is opened longitudinally and the lumen is thoroughly inspected. If the luminal surface is smooth and thrombus-free, subclavian vein reconstruction is performed with a patch angioplasty using a segment of greater saphenous vein or a cryopreserved femoral vein allograft. During this type of reconstruction it is important to extend the patch angiograft along the entire length of the affected vessel, both proximal and
Fig. 24.7. First rib resection, anterior. Following division of the posterior first rib, the anterior portion of the rib is exposed underneath the clavicle and subclavian vein, where it will be divided immediately medial to the scalene tubercle (dashed double line). Fingertip pressure on the posterior stump of the rib facilitates downward displacement of the bone anteriorly, to open the costoclavicular space. A Gertz-Stille rib shears is placed around the anterior portion of the first rib in preparation for division of the bone. Following application of the rib shears, the first rib specimen is removed and the remaining anterior first rib is remodeled with a rongeur to obtain a smooth edge. With permission from Fischer JE, et al., eds. Mastery of Surgery, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2012.

distal to the stenotic segment, including the anterior aspect of the innominate vein. When the subclavian vein is unsuitable for patch angioplasty, due to dense fibrosis within the vein wall, ulceration of the luminal surface, or mural thrombus, the affected segment of the subclavian vein is excised and replaced. In this setting an interposition bypass graft is constructed using a widely beveled end-to-end distal anastomosis to the unaffected axillary-subclavian vein, and an end-to-side
proximal anastomosis extending into the anteromedial innominate vein. Use of a cryopreserved femoral vein allograft is usually preferred for subclavian vein bypass graft reconstruction, since the relatively small size of the saphenous vein requires creation of a panel graft to match the caliber of the subclavian vein, whereas cryopreserved femoral vein allografts of more appropriate diameter are readily available.

An intraoperative upper extremity venogram is always performed at the completion of the procedure, typically performed through the cephalic vein in the distal forearm, to confirm satisfactory reconstruction of the subclavian vein. In many patients a temporary radiocephalic arteriovenous (AV) fistula is constructed at the wrist, as a temporary (12 weeks) adjunct to increase upper extremity venous blood flow after operation. In this event the AV fistula is ligated under local anesthesia and a final follow-up venogram is performed during the same procedure.

Management of Arterial Thoracic Outlet Syndrome

Optimal surgical treatment of ATOS is accomplished through supraclavicular decompression, as described above for NTOS, including removal of the cervical and first ribs. Following decompression, attention is directed toward assessment of the pathologic changes in the subclavian artery in preparation for interposition graft repair. For subclavian artery aneurysms, depending on the length of the vessel exhibiting visible dilatation, satisfactory distal control of the subclavian artery can usually be achieved through the supraclavicular incision alone. When the lesion is more extensive, extending underneath the clavicle, exposure of the axillary artery is accomplished by adding a transverse infraclavicular incision with division of the pectoralis minor muscle tendon. After anticoagulation, clamps are placed on the proximal subclavian artery immediately distal to the vertebral artery and on the distal subclavian artery immediately beyond the aneurysmal segment. The affected segment of subclavian artery is excised and replaced with a direct end-to-end interposition bypass graft. Although reversed saphenous vein grafts may be suitable for subclavian artery replacement they are often too small in caliber, and reconstruction can be readily performed with Dacron or PTFE prosthetic grafts, cryopreserved femoral artery allografts, or other autologous (deep femoral vein or iliac artery) grafts. Following subclavian artery reconstruction a completion arteriogram is performed to evaluate the bypass graft in different positions of the arm, as well as to reassess the distal circulation.

CONCLUSION

There are few conditions in medicine and surgery that elicit more controversy than the management of TOS. In this chapter we present a brief overview of the characteristics of each of the three types of TOS based on the principal structures affected and their varied clinical presentations, the general approaches used in diagnosis and management, and an outline of the surgical procedures most commonly used in operative treatment. While physicians specializing in the management of TOS vary in their individual approaches to diagnosis and treatment, there remains a significant proportion of patients for whom surgical treatment is recommended. Similarly, different surgeons will often prefer one surgical approach over another when considering operative treatment for each form of TOS, and excellent results and outcomes can be obtained by those with abundant experience in this highly specialized area. While it appears likely that the various controversies surrounding optimal treatment for TOS will persist into the near future, there is hope that by accumulating more rigorous clinical evidence we will gradually emerge with a greater consensus upon which to base clinical decisions in the future.

**SUGGESTED READINGS**

The majority of patients with presumed thoracic outlet syndrome when seen by either the thoracic surgeon or the vascular surgeon present with the neurogenic type for which specific diagnostic studies do not exist. As Dr. Thompson points out the diagnosis of neurogenic thoracic outlet syndrome relies almost exclusively on the clinical presentation. A chest radiograph to rule out the presence of a cervical rib probably represents the only imaging study of significant value. Most patients with this upper extremity pain syndrome can derive significant benefit from a specific program of physical therapy that must be continued at least periodically on a chronic basis. For those patients whose symptoms fail to improve with a regimen of prescribed exercises a surgical approach should be considered but patient selection likely represents the most significant predictor of a successful outcome, specifically relief of symptoms.

Most thoracic surgeons prefer the transaxillary as opposed to the supraclavicular approach for resection of the first rib as it may be accomplished without significant manipulation of the neurovascular structures. The anterior and middle scalene muscles are detached from the first rib as the rib is resected in a subperiosteal fashion. Using dedicated first rib instruments, specifically periosteal elevators both grooved and non-grooved, the rib is able to be completely mobilized prior to being cut with first rib cutters. Occasionally resection of the rib is facilitated by dividing the rib at its midpoint and then using downward traction on each segment to more easily expose the anterior and posterior aspects for division.

The supraclavicular approach probably should only be done by those with significant experience in dealing with the thoracic outlet since the potential for injury to the brachial plexus is significant because of the manipulation and specifically the retraction required. Whether or not this approach, with its greater potential for morbidity, results in a higher likelihood of success remains to be determined. Specifically whether the neurolysis advocated by Dr. Thompson adds to the probability of a successful outcome remains unknown but it certainly increases the chance for postoperative neurologic sequelae.

The vascular thoracic outlet syndromes are more straightforward specifically because of the presence of anatomic correlates that confirm the diagnosis. Imaging studies take on an important role in managing these variants of the syndrome. In our experience most of the cases of effort thrombosis of the subclavian vein may be managed by thrombolysis followed closely by transaxillary first rib resection and without any venous reconstruction. Patients are maintained on anticoagulation only for a limited duration following thoracic outlet decompression. The use of venous stents, as Dr. Thompson points out, should be condemned. Management of the arterial variant is guided specifically by the arterial abnormality with decompression of the outlet essentially an adjunct to the arterial repair, albeit an important one.
INTRODUCTION

Indications for chest wall resection are broad and varied. They include resection of both primary and secondary chest wall lesions. Primary chest wall lesions are those that arise within the normal constituents of the chest wall, including skin, connective tissue, muscle, bone, and cartilage. Whether benign or malignant, primary chest wall lesions are relatively uncommon, and resection is often warranted for diagnosis and treatment. Secondary chest wall masses are caused by invasion from a process originating in contiguous organs such as the lung or breast. Lung cancer with chest wall invasion is the most common indication for chest wall resection. In these cases, chest wall resection is performed in stage-appropriate candidates as part of an en bloc resection for attempt at cure.

There are three basic tenets of chest wall resection: (1) resection of all diseases with wide margins, (2) provision of healthy soft tissue coverage, and (3) preservation of respiratory mechanics. The intent of this chapter is to review the indication and techniques of chest wall resection with reconstruction from the simple to the complex. The discussion focuses on the proper selection of reconstructive techniques from "off the shelf" synthetic material to complex soft tissue transfers.

PREOPERATIVE PLANNING

Patients being considered for chest wall resection undergo a complete medical evaluation. Special attention is focused on any past medical or surgical history that will affect the approach for resection and the choices for reconstruction. These factors include previous chest procedures, a history of radiation, evidence of active infection, and immunosuppression. All patients have radiographic imaging, including a chest radiograph and computed tomography (CT) scan of the chest. For patients with a primary chest wall lesion, magnetic resonance imaging may be helpful in delineating the local extent of disease, but as a general rule it cannot distinguish between benign and malignant masses. Patients with underlying lung cancer and contiguous chest wall invasion undergo a complete extent of disease workup to rule out metastatic disease, and if negative, they are considered for resection. If partial vertebral body resection is entertained or there is concern regarding involvement at the level of the neural foramen, preoperative neurosurgical consultation is obtained. Similarly, the need for transfer of large volumes of soft tissue for coverage or unfamiliarity with the available techniques for complex tissue transfer should prompt consultation with an experienced reconstructive surgeon. A tissue diagnosis should be obtained in most cases to differentiate between benign and malignant tumors and to identify malignant neoplasms that may be amenable to medical therapy. This consists of fine needle aspiration, core needle biopsy, or incisional biopsy of lesions larger than 5 cm. Lesions smaller than 5 cm are usually suitable for excisional biopsy.

OPERATIVE PLANNING: OPTIMIZING THE APPROACH

In selecting the appropriate incision, it is imperative that the surgeon be thoughtful, flexible, and experienced. The optimal surgical approach allows for the assessment of the extent of disease without violation of the lesion. Lateral chest wall lesions are generally approached through posterolateral incisions. If there is a planned need for soft tissue transfer, the latissimus dorsi and serratus anterior muscles are mobilized but not divided before entering the pleural cavity. If there is no need for tissue transfer, we generally divide the latissimus dorsi muscle but spare the serratus anterior in case it should be needed in the future. The pleural cavity is entered either at an interspace below the lesion or at a site anterior to the lesion. The lesion is palpated to determine the extent of resection required. Primary chest wall lesions rarely invade the lung, and pulmonary resection is usually not required. In cases of lung cancer with contiguous chest wall involvement, the chest wall resection is performed as shown in an en bloc manner. Attempts to develop an extrapleural plane or strip the tumor off the chest wall should be avoided because this risks violation of the tumor with contamination of the pleural cavity and consequently a high likelihood of recurrence. Once the chest wall resection is complete, the chest wall bloc remains attached to the underlying pulmonary parenchyma while the pulmonary resection is performed. No attempt is made to separate the chest wall bloc from the underlying lung.

Lesions involving the apex of the chest can be approached via the traditional Shaw-Paulson technique. This approach uses a long posterolateral incision carried up to the C7 vertebral body, elevation of the scapula off the chest wall after division of the trapezius and the rhomboids, and chest wall resection from a posterior approach. Recently, it has been recognized that these apical lesions may be more effectively managed through the anterior cervicothoracic approach described by Dartevelle and subsequently modified by others. Anterior chest wall lesions are often best approached with the patient supine and an anterior incision made over the location of the lesion.

Regardless of the surgical approach chosen, the basic tenets of chest wall resection must be fulfilled. These include a wide margin of excision, en bloc anatomic resection with the attached lung parenchyma, and appropriate reconstruction of the chest wall defect when required.

TECHNIQUE OF CHEST WALL RESECTION

Chest wall involvement is often heralded by the clinical finding of pain associated with
a peripheral lesion seen abutting the chest wall on CT scan. In general, it is not possible to reliably differentiate chest wall invasion from simple abutment merely by looking at the CT scan. A posterolateral incision is made, and the latissimus dorsi muscle and serratus anterior muscles are either divided or mobilized if they are needed for pedicled muscle flaps. The chest is typically entered via the fifth intercostal space and exploration carried out. If the lesion involves the fifth rib, entry into the hemithorax should be either anterior or posterior to the presumed area of involvement. Before initiating the chest wall resection, palpation of the hilum and mediastinum should be carried out to ensure resectability. It serves little purpose to take down the chest wall block only to find locally advanced disease or diffuse pleural disease that precludes resection. The combination of mediastinal lymph node positivity and chest wall involvement portends a poor outcome. If there is any suspicion of nodal involvement, mediastinoscopy must be carried out before chest exploration. A positive mediastinum usually precludes chest wall resection outside of a protocol setting, although some surgeons proceed with resection after neoadjuvant chemotherapy. Most studies have shown essentially no 5-year survivors with chest wall involvement and positive mediastinal lymph nodes.

Once it has been determined that the tumor is resectable, the chest wall resection is begun. Depending on the location, the scapula may need to be mobilized off the chest wall, which requires division of the trapezius and rhomboid muscles. At least a portion of one rib above and one rib below the lesion should be resected. The extent of resection is determined by the intrathoracic exploration. The anterior portion of the resection is done first by determining the appropriate rib and incising the periosteum several centimeters anterior to the lesion. A wide excision should be performed to ensure negative margins. We prefer to take a 1-cm piece of rib and submit this separately at each level as the anterior resection margin (Fig. 25.1A). This move creates a small amount of space for ligation of the intercostal bundle at each level. Starting at the inferior extent of the resection and working superiorly, the anterior margin is taken at each level with the pleura excised as the resection proceeds. The intercostal muscles at the inferior and superior extent of the resection are divided along with the pleura, and the posterior portions of the

Fig. 25.1. (A) En bloc chest lateral chest wall resection in a patient with a primary lung cancer. The anterior line of resection is far away from the primary site of invasion, and small, 1-cm portions of the anterior ribs are removed and labeled as margins. (B) The completed chest wall resection; at this juncture, the entire chest wall bloc is allowed to fall into the pleural cavity and the pulmonary resection is performed through the chest wall defect. (C) Disarticulation of the posterior rib from the transverse process with an osteotome. (Reprinted with permission from Kaiser LR. Atlas of General Thoracic Surgery. St. Louis, MO: Mosby; 1997.)
involved ribs are divided. There is no need to take a separate posterior margin at each level as is done anteriorly; this margin will be marked on the en bloc resection specimen. Depending on the location of the lesion, the posterior rib division may be either through the rib as demonstrated in Figure 25.1B or may require disarticulation of the rib from the respective transverse process of the spine as shown in Figure 25.1C. If there is any doubt, the rib should be disarticulated and, at times, even the transverse process may need to be resected. As always the intent is to have a negative resection margin; anything less (i.e., a positive margin) is associated with poor long-term survival.

If required, division of the posterior portion of the ribs is performed in a subperiosteal manner with ligation of the intercostal bundle. The bundle at each level has already been ligated and divided anteriorly, and thus only a single ligature at each level is necessary. If disarticulation from the transverse process and vertebral body is required, the intercostal muscle must be ligated at the level of the neural foramen. To disarticulate the ribs from the transverse process, the paraspinal ligament must be reflected away from the spine down to the level of the transverse process with the use of electrosurgery because there are numerous perforating vessels that must be controlled. Once down to the transverse process, the rib is retracted anteriorly as the cautery incises the cartilaginous junction between the neck of the rib and the transverse process of the spine. The correct location has been identified when the cartilage appears to “melt” with the application of the cautery and the rib neck begins to separate slightly. Once the cartilaginous symphysis is divided, a curved osteotome is inserted between the neck of the rib (Fig. 25.1C, inset) and the transverse process and, with the transverse process as a fulcrum, is rocked forward, thereby disarticulating the neck of the rib from the transverse process and the head of the rib from the vertebral body. This is facilitated by having incised the overlying pleura from within the chest. The osteotome is directed anteriorly toward the vertebral body, and thus away from the spinal canal, so there is no chance of injuring the spinal cord. The force is directed upward away from the vertebral body so as to lift the head of the rib. The rib should be gently disarticulated so as to not avulse the intercostal nerve as the dural sheath may be torn with a resultant cerebrospinal fluid leak. Once the rib has been disarticulated enough to see the intercostal nerve exiting the neural foramen, the nerve and intercostal vessels should be ligated and divided. It is not uncommon to experience some bleeding from the foramen because there may be multiple small venous channels that may be opened. Only bipolar cautery should be used at the foraminal level to control any bleeding so as to prevent any thermal injury to the spinal cord. The foramen should not be packed with Surgicel or gel foam to control bleeding; these materials can expand within the foramen leading to spinal cord compression with catastrophic neurologic consequences.

Once the chest wall bloc has been entirely separated, it is left attached to the underlying lung parenchyma in cases of a primary lung tumor invading the chest wall. The appropriate anatomic pulmonary resection (lobectomy or, at times, segmentectomy) is then carried out. A complete mediastinal lymph node dissection should be part of the procedure even if a mediastinoscopy has been done so that the most accurate staging information is obtained. If the lesion is a primary chest wall tumor, the specimen is removed and the reconstruction is begun.

Removal of the first rib requires some special techniques and expertise. One must be intimately familiar with the relationship of the brachial plexus and subclavian vessels to the first rib to avoid injuring any of these structures. Special first-rib instruments are necessary for safe first-rib resection. These include special angled first-rib periosteal elevators either with a groove or not, rongeurs, and angled rib cutters. If first-rib resection is required, the scalene muscles that insert on the rib must be detached. The posterior scalene inserts on the second rib, so this will have already been taken. The middle scalene inserts on the first rib between the subclavian vein and artery and should be reflected with the periosteal elevator following cautery incision of the periosteum. The anterior scalene should be incised and reflected off the rib. The inferior aspect of the rib is freed with the use of a grooved elevator. A Matson elevator is placed under the rib to expose the medial aspect so as to protect the nerves and vessels. Once the medial aspect of the rib is cleared, a first-rib cutter is used to cut the anterior aspect of the rib. If the first rib needs to be disarticulated from the transverse process, care must be taken to identify the C8 and T1 nerve roots that combine to form the lower cord of the brachial plexus. These nerve roots may be identified by visualizing the head of the first rib, which is located immediately between these two structures. If the roots are not identified as they exit their respective foramina, the operator may mistakenly divide the lower cord of the brachial plexus leaving the patient with a useless ipsilateral hand. The T1 root may be taken as part of the resection if it is involved, but division of the C8 root leaves a nonfunctional hand. The degree of disability that occurs after division of the T1 nerve root usually is minimal to moderate at most.

Recent advances in chest wall resection include the use of thoracoscopy, particularly in cases where thoracoscopic lobectomy with en bloc chest wall resection is anatomically feasible. Some surgeons advocate this technique based on the theoretical benefit of alleviating rib spreading, thereby reducing postoperative pain and recovery time. More extensive studies must be performed to validate the use of this technique.

**SYNTHETIC MATERIAL CHOICES**

The synthetic materials available for chest wall reconstruction are polypropylene mesh and polytetrafluoroethylene patches. Both have been used in large series of patients and appear to provide equivalent outcomes. Polypropylene is significantly less expensive and can be reinforced with methylmethacrylate to create a rigid prosthesis that can be contoured to the chest wall. This may provide a better cosmetic result and a significantly better functional result especially for anterior lesions. Figure 25.2 shows the creation of a mesh/methylmethacrylate “sandwich” for chest wall reconstruction. Regardless of the material selected for reconstruction, it is inserted into the defect with interrupted, nonabsorbable suture. We use No. 1 polypropylene sutures placed through the cut edges of the lateral ribs and around the uncut superior and inferior ribs as shown in Figure 25.3. A small drill facilitates placement of suture through the cut ribs. If no superior rib remains for fixation, the prosthesis is secured on the remaining three sides with room at the apex to avoid compression of the structures of the thoracic inlet. The synthetic material is covered with healthy soft tissue; usually, this simply requires closure of the cut muscle edges over the prosthesis followed by soft tissue closure. In cases where there has been significant soft tissue or muscle resection, complex soft tissue transfer is required.

Reconstruction of the chest wall defect is not required if a posterior resection has been done and the entire defect is covered by the scapula. If the fifth rib has been taken, however, the tip of the scapula has

*The neurovascular bundle that must be preserved in each flap is listed. These transfer flaps as well as a variety of others can also be used as "free flaps" with the use of microsurgical techniques to establish arterial inflow and venous drainage in complex cases.

There is a tendency to become trapped underneath the sixth rib, a situation that is very uncomfortable for the patient. Thus, if the fifth rib has been taken posteriorly, chest wall reconstruction with a patch of polypropylene mesh should be undertaken to prevent entrapment of the scapular tip. Rigid fixation is not required in this location. Other posterior or posterolateral chest wall defects should be reconstructed either with polypropylene mesh alone or with mesh and methylmethacrylate. Anterior chest wall defects usually require a rigid prosthesis to prevent respiratory embarrassment due to altered chest wall dynamics in the early postoperative period. This is especially important in the patient with borderline pulmonary function, where the "flail chest" physiology created by the chest wall defect is often enough to mandate mechanical ventilation without rigid fixation of the chest wall.

Several commercially available osteosynthesis systems are now being utilized for complex chest wall reconstruction. These consist of either steel or titanium rib prostheses fixed in place with modular connectors or silicone molds into which methylmethacrylate can be injected. Although more expensive, these systems may provide a structural advantage in the preservation of chest wall mechanics. It is important to note, however, that implantable materials always carry the risk of infection or displacement. Additionally, most authors still advocate coverage with mesh or tissue flaps.

**TISSUE TRANSFER OPTIONS**

The major muscles of the chest wall provide a good source of autologous tissue for soft tissue coverage of large chest wall defects. They may be utilized to cover prosthetic material in cases where significant soft tissue has been removed or alone without underlying prosthetic reconstruction in cases of infection. The rectus abdominis and omentum can also be transferred from the abdomen to the chest to provide coverage. Table 25.1 lists the tissue available to transfer to the chest along with the blood supply of each flap. Preservation of the neurovascular bundle of a pedicled flap is critical to its success and is an absolute requirement.

Figure 25.4 illustrates the anatomic features of each pedicled flap used in the chest. Anterior chest wall coverage is best provided by pectoralis major advancement flaps. A pedicled rectus abdominis flap or omental flap with skin graft may also be
utilized. Lateral defects are best addressed with pedicled serratus and/or latissimus flaps. If a composite flap (skin, soft tissue, and muscle) cannot be used, muscle alone can be transferred and a split-thickness skin graft can be applied.

**STERNAL RESECTIONS**

Primary sternal tumors are rare, and when they occur they almost always are chondrosarcomas arising from the body of the sternum. These tend to be low-grade lesions, and the best opportunity for cure is total sternectomy to achieve negative margins and immediate reconstruction with prosthetic material. The likelihood of cure and propensity for recurrence with sarcomas are related to the tumor’s histologic grade.

Defects created by partial sternectomy may be small and reconstructed with simple pectoralis advancement flaps without the need for prosthetic material. Total sternectomy results in significant soft tissue and structural loss and usually requires complex reconstruction. This is especially true if the sternum is being resected for recurrent breast cancer after excision and radiation therapy.

**TECHNIQUE FOR STERNAL RESECTION**

A vertical midline incision is made over the sternum, and skin flaps may need to be raised, depending on the size of the lesion. The pectoralis muscles are reflected laterally unless muscle is involved, in which case they are left with the sternum to be resected en bloc. The sternal notch is dissected and the retrosternal plane is developed. Inferiorly, the xiphoid process is excised and the retrosternal plane entered from this aspect as well. The pleural reflections are swept laterally. The costal cartilage at each level is divided after removal of the perichondrium. The posterior perichondrium is incised to separate it from the sternum. This is facilitated by the use of a bone hook to elevate the sternum.

Often the manubrium can be preserved with total removal of the body of the sternum. If this is the case, the body of the sternum is disarticulated from the manubrium. If resection of the manubrium is required to achieve a complete resection, the clavicular heads are disarticulated and the first costal cartilage on each side incised. This allows complete removal of the sternum. Reconstruction is carried out with a polypropylene mesh/methylmethacrylate “sandwich,” which is fitted into the defect and contoured appropriately. The prosthesis is inserted with monofilament nonabsorbable suture placed through the cut rib edges and clavicular heads.

Figure 25.5 illustrates an intended total sternectomy for a primary sternal lesion. The reconstruction is completed as shown in Figure 25.6A. The omentum has been transferred to cover the mediastinum; a mesh/methylmethacrylate prosthesis is covered by bilateral pectoralis major turnovers. If the skin is not removed as part of the resection, it is closed over drains to complete the reconstruction. If significant skin and soft tissue has been resected, the prosthesis can be completely covered with the addition of a rectus abdominis flap (Fig. 25.6B) and a split-thickness skin graft applied.

**CONCLUSION**

Primary and secondary lesions of the chest wall and sternum can be resected in appropriate patients with good clinical outcomes. Taking on these cases requires proper preoperative planning and a working knowledge of a variety of reconstructive techniques.
Section I: General Thoracic Surgery

Fig. 25.5. Primary sternal tumor with intended resection lines.

Fig. 25.6. (A) Reconstruction of sternal resection with omental transfer to cover the mediastinum followed by bilateral pectoralis muscle turnover flaps to cover a polypropylene mesh methylmethacrylate prosthesis. If soft tissue and skin coverage is also needed, the prosthesis can be completely covered by a rectus flap as shown (B) and the reconstruction completed with a skin graft.
Primary lung tumors involving the chest wall are unusual but the surgeon must be knowledgeable regarding resection techniques since chest wall involvement usually cannot be determined with certainty preoperatively. In order not to compromise the extent of the resection, the surgeon must also be intimately familiar with the techniques of chest wall reconstruction. The importance of achieving a negative resection margin must be again emphasized since this along with node negativity are the major determinants of long-term survival. There should be no hesitation about making a “big hole” if that is what is required to achieve a negative margin. In order to guide the pathologist, at least two of the margins of the resected chest wall specimen should be marked with sutures and indicated on the pathology requisition. Frozen section confirmation of bone margins is not possible so the lesion should be resected widely.

As the authors point out the combination of chest wall involvement accompanied by positive mediastinal lymph nodes portends a very poor outcome and thus a careful assessment of the mediastinum should be carried out if there is any question of node positivity. Certainly if the PET scan shows activity in the mediastinum, histologic confirmation should be obtained either with endoscopic ultrasound-guided bronchoscopic biopsy or mediastinoscopy prior to considering resection.

Apical chest wall involvement creates a unique set of issues that require special expertise as the authors point out. Because of the complex anatomy and myriad structures within the thoracic inlet, great care must be taken during resection and the surgeon must be prepared for a variety of situations. If the T1 nerve root is involved it may be taken with little if any neurologic sequelae in the majority of cases. However, care must be taken to unequivocally establish that one has identified the T1 root and not mistake it for the lower cord of the brachial plexus. This is only possible if the C8 and T1 nerve roots are identified at the foraminal level where the head of the first rib is seen between the roots and the confluence of the two roots is seen to form the lower cord. Then, and only then, should the large T1 root be divided. If the tumor extends further superior and is seen to involve the lower cord of the brachial plexus or the C8 nerve root resection should not be performed as this will leave the patient with a useless, clawed hand. Additionally, the subclavian artery may be involved by tumor and the surgeon should be prepared for this possibility that involves resection of the involved segment of artery with prosthetic graft replacement. The possibility of neurovascular involvement further underscores the importance of the surgeon being familiar with the anterior approach to apical lung tumors as opposed to the classic Shaw–Paulson posterior approach. The anterior approach is far less morbid and provides significantly better exposure to the neurovascular structures without compromising the ability to achieve an adequate resection of chest wall especially the first rib. One would think that an anterior approach for a posterior lesion is counterintuitive but one must keep in mind the very short anterior–posterior length at the chest apex. In addition, the upper lobectomy is easily accomplished through the anterior cervicothoracic incision with no need for any additional incision.

Primary chest wall tumors are exceedingly rare, as the authors correctly point out and definitive histology needs to be established prior to proceeding with resection because many of these turn out to be “medical tumors” best treated with chemotherapy and potentially radiation therapy. I am specifically referring to Ewing’s tumors and chest wall lymphomas, among others. Small lesions may be completely excised for “biopsy,” while larger lesions should have an incisional biopsy for the establishment of definitive histology on permanent section. Frozen section diagnosis should not be relied upon when dealing with these lesions. The biopsy procedure should be a separate procedure followed by the definitive procedure at a second session once the histology has been established and resection is indicated.
INTRODUCTION

Separating the thoracic and abdominal cavities, the diaphragm is a dome-shaped muscular structure that serves its key function as the principal muscle of respiration. Through contraction and relaxation, the diaphragm cyclically increases and decreases the volume of the thorax, altering intrathoracic pressure and, ultimately, permitting air entry into the lungs via the establishment of negative pressure. Sustained contraction of the diaphragm serves to increase intraabdominal pressure, useful in generating a Valsalva effect. When functioning well, the diaphragm rarely is the subject of significant clinical attention; however, dysfunction of the diaphragm poses significant and challenging dilemmas to the patient and the surgeon, emphasizing the substantial importance of this musculoaponeurotic structure.

EMBRYOLOGY AND ANATOMY

The embryologic development of the diaphragm occurs between the 7th and 10th weeks of gestation, with the definitive musculotendinous diaphragm incorporating elements of four embryonic precursors: (1) the septum transversum, (2) the pleuropertitoneal membranes, (3) the paraxial mesoderm of the body wall, and (4) the esophageal mesenchyme. From the septum transversum, myoblasts migrate into the right and left pleuropertitoneal membranes, bringing phrenic nerve branches along the way. The majority of the septum transversum gives rise to the nonmuscular diaphragmatic central tendon. The posterolateral portion of the diaphragm is formed by fusion of the dorsal mesentery with the pleuropertitoneal membranes. As these membranous structures are encountered by muscle fibers migrating caudally from the cervical myotomes, the muscular bulk of the diaphragm is formed. Migration of myoblasts into the dorsal mesentery results in formation of the bilateral crura, which originate on the vertebral column and insert into the dorsomedial diaphragm.

While the diaphragm is a fairly consistent organ, with no normal variations in anatomic structure, there are several common abnormalities that result from failed intrauterine development. As the diaphragm originates from several embryonic structures, and normal development requires complex and coordinated execution of a number of vital steps, congenital abnormalities of the diaphragm are well described. Such errors in embryologic development can result in future surgical problems, including congenital diaphragmatic hernias and eventration. Presence or absence of a sac depends on the time point at which the defect occurs, either before or after membranous fusion.

To safely operate on or near the diaphragm, one must have a clear understanding of the anatomic features of the muscular organ, as well as appreciation for the vital structures in close proximity. With its dominantly convex superior surface facing the thoracic cavity and the concave inferior surface facing the abdomen, the diaphragm consists of a mobile component centrally and a fixed component peripherally, which attaches to the inferior margin of the thoracic cage and the superior lumbar vertebrae. The peripheral muscular fibers converge radially at the central tendon. This fibrous, centrally located aponeurosis is composed of the right, left, and middle leaflets, resembling somewhat of a cloverleaf with incomplete divisions. The major muscular elements of the peripheral diaphragm include the sternal, costal, and lumbar groups (Fig. 26.1). The sternal portion is comprised of two muscular attachments to the posterior xiphoid. The costal portion comprises the right and left domes of the diaphragm, attaching to the inferior six ribs and adjacent costal cartilages. The lumbar portion arises from the medial and lateral arcuate ligaments (thickened extensions of the psoas and quadratus lumborum fascias, respectively) and attaches to the three most superior lumbar vertebrae.

The left and right crura of the diaphragm arise from the anterior aspects of the lumbar vertebrae. The right crus is longer than the left, and may arise from the first three to four lumbar vertebrae, while the left crus may arise from just the first two to three vertebrae. As the muscle fibers ascend, the medial fibers of both crura decussate just anterior to the aorta. After encircling the esophagus, the muscle fibers insert superiorly into the central tendon of the diaphragm. The central tendon is fused to the inferior aspect of the pericardium via the phrenicopericardial ligaments.

Significant structures pass through three openings: the caval foramen, at T8; the esophageal hiatus, at T10; and the aortic hiatus, at T12 (Fig. 26.2). The caval opening, lying within the central tendon, allows the passage of the inferior vena cava (IVC) as well as terminal branches of the right phrenic nerve and some lymphatic channels. The esophageal hiatus is to the left of midline but is dominantly a formation of the right crus. In addition to the esophagus, this aperture also provides a path for the anterior and posterior vagus nerves, esophageal branches of the left gastric vein and artery, and lymphatics. The aortic hiatus is formed by the crura and the median arcuate ligament, and allows passage of the aorta as well as the thoracic duct.

The major blood supply to the inferior aspect of the diaphragm comes from the left and right phrenic arteries, which come directly from the abdominal aorta in the vicinity of the aortic hiatus (Fig. 26.3). These paired arteries each bifurcate, giving off a large anterior branch that courses along the anterior and superior aspects of the muscle, and merging with the pericardiophrenic artery. The posterior branches of the phrenic artery course laterally and posteriorly and ultimately merge with the intercostal vessels. The pericardiophrenic and intercostal vessels originate from the internal mammary artery. Dominant venous drainage occurs via the
inferior phrenic veins, which drain into the IVC on the right, and both the IVC and the adrenal vein on the left.

Motor innervation of the diaphragm comes exclusively from the phrenic nerves (Fig. 26.2). These nerves arise from C3–C5, coming down through the thorax posteriorly, and moving anterolaterally over the pericardium. On the left, the phrenic nerve enters the diaphragm just lateral to the cardiac border and, on the right, the nerve enters the diaphragm just lateral to the caval hiatus. The phrenic nerves, supplying all motor and some sensory innervation of the diaphragm, are made up of four trunks: sternal, crural, anterolateral, and posterolateral. The nerves first give off the sternal branch, then penetrate the diaphragm and course along the inferior surface of the diaphragm. The peripheral portions of the diaphragm receive some sensory fibers from the intercostal and subcostal nerves, as well.

NORMAL FUNCTION

As the chief muscle of inspiration, the diaphragm descends during inspiration and rises during expiration. The right dome may reach as high as the level of the 5th rib and the left dome may ascend to the 5th intercostal space. The exact level of the diaphragm will vary with the phase of respiration, the patient’s position (supine vs. upright), and the volume occupied by the abdominal viscera. Contraction of the diaphragm results in flattening of the domes, increasing the intrathoracic volume, and permitting negative pressure and entry of air into the chest.

In addition to its important role in ventilation, contraction of the diaphragm also has a significant impact on circulatory function, with changes in intraabdominal and intrathoracic pressures aiding in appropriately timed increases in venous return. Further, contraction of the diaphragm may alter intraabdominal pressures such as to facilitate emesis, defecation, and bladder emptying.

SURGICAL CONSIDERATIONS

When operating on or near the diaphragm, familiarity with the path and anatomic location of the phrenic nerves is of great importance. Preservation of diaphragmatic function is best achieved through intraoperative awareness of phrenic innervation and careful placement of incisions when opening the diaphragm for access or excision. Depending on the goals and details of the specific operative procedure, one of several common incisions may prove useful.
Fig. 26.2. Anatomy of the diaphragm with the branches of the phrenic nerve as viewed from the abdomen. The sternal branch of the phrenic nerve is seen in Figure 26.1.

IMAGING AND FUNCTIONAL EVALUATION

Prior to operating on the diaphragm, appropriate diagnostic studies should be obtained to confirm presumed diagnoses and to characterize relevant anatomic and physiologic features. Chest radiography serves as a useful initial study for a variety of diaphragmatic abnormalities, and may be followed by additional tests for diagnostic confirmation and further elucidation of specific pathologic features and relevant anatomy. Cross-sectional imaging, via computed tomography (CT) and magnetic resonance imaging (MRI), may provide needed details regarding diaphragmatic defects and neoplastic processes and their relationships with surrounding structures.

When concern has been raised for functional deficits of the diaphragm, the test of choice is termed a “sniff test.” This imaging study, performed under fluoroscopy, involves dynamic imaging of the diaphragm with observed sniffing. In this test, a dysfunctional hemidiaphragm should demonstrate paradoxical movement with the degree of paradoxical movement having clinical relevance. Dynamic breathing MRI can also be used to assess diaphragm function in the setting of concern for diaphragmatic paralysis. Phrenic nerve stimulation may be additionally helpful in evaluating diaphragm function in the setting of neuromuscular disorders.

SPECIFIC DISORDERS AND MANAGEMENT

Congenital Defects

Morgagni Hernia

The hernia of Morgagni is an anterior, retrosternal diaphragmatic defect, occurring between the xiphoid and the costochondral attachments of the diaphragm (Fig. 26.5). Relatively rare, this embryologic failure of myoblast migration accounts for less than 1 in 50 cases of diaphragmatic defects. With this defect, abdominal contents tend to herniate on the patient’s right, with the left-most aspect of the defect occupied by pericardium. While this congenital defect is present at birth, symptoms are relatively minor, and, oftentimes,
patients do not present until adulthood. Increased abdominal pressure, such as with obesity or pregnancy, tends to precipitate increased symptoms, frequently leading to the diagnosis. These symptoms may range from vague fullness to bowel obstruction, and in some patients the defect may be identified incidentally upon radiographic evaluation performed for unrelated indications. Regardless of the extent of symptoms, operative repair is performed for all appropriate surgical candidates in order to prevent complications of obstruction and ischemia.

Repair of Morgagni hernias is typically performed via an abdominal approach. Either a midline or subcostal incision will facilitate appropriate visualization and exposure. Laparoscopic repair is also well described. For those circumstances in which herniated structures appear to be fixed high in the chest, a transthoracic approach may be required for adhesiolysis and sac reduction. After gaining access, attention should be directed toward reducing contents of the sac using gentle traction, taking care to avoid injury to involved organs. The sac is then resected. Following reduction and resection of the hernia sac, repair of the diaphragm is performed. The defect may, potentially, be closed primarily if there remains a reasonable margin of muscular tissue around the defect. Closure is performed with heavy nonabsorbable suture placed in an interrupted fashion (Fig. 26.6). In the absence of a complete muscular rim, the defect will require attachment of the free muscle edge to the costal margin. One should also note that if a primary repair results in excessive tension, nonabsorbable mesh or a polytetrafluoroethylene (PTFE) patch should be placed to close the defect between the diaphragmatic rim and the chest wall. If the pleural space is entered, a chest tube should be placed at the end of the procedure.

**Bochdalek Hernia**
Congenital failure of the closure of the pleuroperitoneal canal results in a posterolateral diaphragmatic defect, permitting herniation of the foregut structures as they return into the abdominal cavity (Fig. 26.5). The majority of these defects tend to be left sided (>85%), and they are often associated with significant cardiac anomalies. Major morbidity results from the space occupation in the chest by the abdominal organs, ultimately hindering normal lung development. The subsequent pulmonary hypoplasia renders many of these patients critically ill, during the delivery and neonatal periods, ultimately causing substantial morbidity and mortality.

Diagnosis is typically made by prenatal ultrasound, which facilitates advanced planning for delivery, perinatal care, and operative intervention. Postnatal diagnosis is most often made after chest radiography demonstrates intestinal contents in the thoracic cavity. As mentioned, this structural defect is accompanied by physiologic abnormalities, often including some degree of pulmonary hypoplasia as well as pulmonary hypertension. A number of important recent advances have been made in improving the care for patients with this
Fig. 26.4. Thoracic view of the diaphragm showing the common diaphragmatic incisions and their relationship to the branches of the phrenic nerve.

condition, including improved prenatal detection, extracorporeal membrane oxygenation (ECMO), and recognition and treatment of severe pulmonary hypertension. Lung protection strategies, such as the use of high-frequency oscillatory ventilation (HFOV) and adherence to airway pressure limitations, have been employed to limit barotrauma. However, despite these treatment advances, overall survival remains in the range of 60% to 70% dependent to a significant extent on the severity of the abnormality. Due to the high prevalence of associated anomalies, thorough evaluation should be undertaken to identify any other major congenital conditions prior to consideration of operative intervention. While plans for operative intervention should be initiated upon diagnosis, repair should not be performed emergently. Infants should be placed on mechanical ventilation, undergo nasogastric decompression, and have nutritional needs addressed, allowing stabilization in the neonatal intensive care unit preoperatively. Once the infant has been physiologically optimized and the presence of other major congenital anomalies has been investigated, operative repair may be considered.

A number of protocols have been described with regard to timing of operative repair. In general, preoperative goals include radiographic clearing of lung fields, optimization of tidal volume in the setting of minimal positive end expiratory pressure (PEEP), approximation of euvoeia, and demonstration of maximized right ventricular function. Repair may be performed on or off ECMO, and outcomes with each vary among institutions. The operative procedure is performed through a subcostal abdominal incision, and, after facilitating appropriate exposure, the hernia contents are gently reduced. Hernia sacs are present in a minority of cases, but should be uniformly sought and resected if present. Edges of the defect should be identified, and an assessment should be made regarding feasibility of primary repair, which should only occur in the setting of adequate tissue that can be brought together without tension. Prior to closing the defect, a chest tube should be placed under direct visualization. If primary repair is feasible, this can be performed with nonabsorbable interrupted sutures placed in a mattress fashion. Large defects may require prosthetic mesh that should be stitched in place with nonabsorbable, pledgeted sutures (Fig. 26.7). In the absence of a posterior muscular rim, it may be necessary to suture the prosthesis directly to the ribs and intercostal musculature. Once the diaphragm has been repaired, as the abdominal viscera are returned to their appropriate locations and attempts are directed toward closing the abdomen, inadequate abdominal domain may pose a dilemma. This can be dealt with by using mesh to bring the abdominal wall together without tension, by closing the skin only (resulting in a ventral hernia), or use of a silo. Even after a well-timed and carefully executed operative repair, patients may remain critically ill and in a tenuous cardiopulmonary state postoperatively. Ongoing efforts must continue to achieve the best possible outcomes for these infants.
Acquired Defects

Hiatal Hernia

Hiatal hernias are categorized into four subtypes, with the most common being the type I sliding hernia. The type I hiatal hernia and its management are discussed elsewhere in this book, in terms of evaluation and treatment for gastroesophageal reflux disease. Type II, or paraesophageal, hernias involve a focal weakening of the phrenoesophageal membrane anterolateral to the esophagus, permitting herniation of the gastric fundus and antrum despite intraabdominal fixation of the distal esophagus and gastric cardia (Figs. 26.5A and 26.8B). Obstruction may then occur at the level of the diaphragm, with the stomach additionally at risk for volvulus and ischemia. Type III is comprised of both a type I and type II, while type IV involves generalized enlargement of the hiatus with multiple abdominal viscera in the chest.

Patients with paraesophageal hernias may report some substernal fullness, postprandial discomfort, or symptoms of reflux. Many of these patients may not be symptomatic at all, or may be diagnosed only when they present with complications of the hernia. Those patients presenting with volvulus or obstruction may be critically ill with severe pain and nausea and will require emergent operative intervention to prevent strangulation. Historically, it was widely recommended to repair all paraesophageal hernias, regardless of symptom profile. More recent attention has been given toward potentially observing asymptomatic patients, particularly those that are high risk for operative intervention.

In repairing paraesophageal hernias, several approaches have been described. Traditionally, this involved thoracotomy for hernia reduction, followed by laparotomy for Belsey or Nissen fundoplication, and, when appropriate, Collis gastroplasty. While this strategy is still employed, our preferred approach is via laparoscopy. Our technical approach to giant hiatal hernia repair requires consistent emphasis on several key operative points, tenets that hold the surgeon to the same principles of

Fig. 26.5. Abdominal view of the diaphragm showing the location of the common hernias.

Fig. 26.6. Repair of hernia of Morgagni. Abdominal approach when an anterior rim of muscle is present.
open surgery, and consequently result in comparable outcomes.

After gaining laparoscopic access, attention is directed toward reduction of the stomach. The stomach itself is not grasped directly; rather, the apex of the hernia sac is grasped and inverted by pulling caudally, and the sac is opened well away from the crural edge. Dissection is carried into the mediastinal areolar tissue plane, allowing the stomach to fall into the abdomen. Care is taken to maintain crural integrity without exposing the crural muscle fibers. Following division of the sac, the fat pad is dissected circumferentially. In this process, by staying right on the surface of the muscle fibers of the esophagus and stomach, the vagal nerves should be successfully preserved. The crura are then closed in an interrupted fashion with nonabsorbable #1 sutures and intracorporeally tied knots, reinforced with pledgets, for approximately two-thirds of the anteroposterior distance. Use of standard suture and needles allows for appropriately sized,
full-thickness crural bites, replicating the crural closure achieved in open operations.

After closing the crura, the intraabdominal portion of esophagus is assessed for adequate length, and if found to be less than 2.5 cm, a wedge Collis gastroplasty is performed over a 46F bougie. The greater curve of the stomach is held anteriorly and inferiorly, and stapler brought through the left upper quadrant is positioned nearly perpendicular to the direction of the bougie. A second stapler load is typically necessary from this angle, followed by one or two stapler loads from the right paramedian location.

In our practice, a Nissen fundoplication is next performed over a bougie, constructed with three stitches of 2-0 silk, incorporating a moderate bite of esophagus into each stitch. Ensuring adequate (but not too much) tension is of key importance. After constructing the wrap, three stitches of 2-0 silk are used to anchor the top of the fundus to the crura (Fig. 26.8C). In some circumstances, we complete the repair with a biologic mesh buttressing of the closed hiatal defect, based on multiple studies suggesting a decrease in recurrence when mesh is employed. While open procedures remain efficacious for paraesophageal hiatal hernia repair, reports from centers of excellence have demonstrated that a minimally invasive approach can be performed safely and with comparable results, thus sparing patients the morbidity of a more invasive operation.

Trauma

The management of traumatic injuries to the diaphragm depends upon the timing of presentation; injuries presenting in the acute setting may be approached differently than those diagnosed after a period of chronicity. Such injuries may be secondary to blunt or penetrating trauma, with motor vehicle accidents accounting for the majority of blunt mechanisms and knife and gunshot wounds comprising most of the penetrating injuries.

Diaphragmatic injuries in the setting of blunt trauma require mechanisms associated with a tremendous amount of force, and are often accompanied by a number of additional and severe injuries. Acute rupture of the diaphragm from blunt injury occurs much more frequently on the left than on the right, upon transmission of force from the abdominal viscera upward. On the right, the liver serves to absorb some of the transmitted energy, thus resulting in fewer right-sided diaphragmatic injuries.

Penetrating trauma tends to be a more frequent cause of diaphragmatic injury than blunt trauma. As opposed to blunt mechanisms of injury, these cases typically occur with more focal (rather than diffuse) concomitant injuries. In patients with penetrating injuries to the chest, a plain radiograph obtained in the trauma bay may reveal abdominal viscera in the thoracic cavity, indicating a diaphragmatic rupture. However, defects may not always result in immediate herniation. For patients with penetrating injuries to the chest that do not meet criteria for operative exploration, close follow-up is useful in identifying any diaphragmatic injuries missed at initial evaluation. For patients with penetrating wounds to the abdomen, operative exploration is often mandated, and the diaphragmatic defect can be found intraoperatively. Careful evaluation of the diaphragm is essential to avoid late herniation through an unnoticed defect. Laparoscopy has been used both for evaluation and repair of diaphragmatic defects in this setting. The authors caution the use of laparoscopy for this application as a thorough and complete evaluation is often tremendously challenging, especially as it relates to full evaluation of the posterior portion of the diaphragm.

Patients undergoing exploration for acute traumatic injury are typically approached via midline laparotomy. Diaphragmatic repair, while important, should be performed following management of any life-threatening hemorrhage or other significant visceral injury. Areas of nonviable tissue should be excised. Traumatic diaphragmatic defects can usually be repaired primarily. If mesh is used and a phrenic nerve injury appears to have
occurred, care should be taken to ensure that the mesh is taut so as not to allow paradoxical diaphragmatic motion in the future.

The late or delayed identification of diaphragmatic injuries requires a different approach, as abdominal viscera may be involved by extensive adhesions in the chest. Even if patients have been asymptomatic for a prolonged latent phase, operative repair is necessary to prevent obstructive complications. The traditionally described approach for this operation was via thoracotomy in order to permit adhesiolysis and visceral reduction. However, in recent years, a number of techniques employing thoracoscopy and/or laparoscopy have been described. If the hernia contents appear above the level of the inferior pulmonary vein, an intrathoracic approach is typically safest. For patients with larger defects, thoracoscopy may prove challenging due to visual obstruction by the herniated viscera. Regardless of the type of access used, the operative principles are the same. Abdominal contents are gently reduced, the hernia sac is excised, and the defect is repaired. If the defect comes together primarily without tension, this can be performed with interrupted nonabsorbable sutures; however, mesh patches may be necessary if a primary repair would result in undue tension thus increasing risk of disruption and recurrence.

Eventration and Paralysis

While diaphragmatic eventration and paralysis occur as two discrete pathologic entities, they share similar physiologic manifestations, and thus surgical treatment—when indicated—is similar in approach. Eventration is a congenital abnormality resulting from failed development of the muscular portion of the diaphragm, with maintenance of the normal attachments to the sternum, ribs, and spine. Grossly, the affected diaphragm appears thinned and attenuated, and is functionally ineffective during respiration. While more common on the left, this defect may be unilateral or bilateral, and may affect just a portion or an entire hemidiaphragm.

Clinically distinct from eventration, acquired paralysis or paresis of the diaphragm may occur in several clinical settings, with the most common etiologies being phrenic nerve trauma after cardiac surgery and encroachment of thoracic malignancies upon the phrenic nerve. In the postoperative setting following cardiac procedures, paralysis may be due to traction on the nerve, pressure from a retractor, thermal injury resulting from techniques used to cool the heart, or associated with the use of cautery in the vicinity of the nerve. This deficit, at times, may be
temporary in nature. Less common causes of phrenic nerve dysfunction include trauma, neuromuscular disorders, or infectious processes. A number of cases are also idiopathic, with no clear inciting factor prior to development of diaphragmatic dysfunction.

As both of these processes result in ineffective caudal excursion of the diaphragm during inspiration, symptoms may be similar but especially with eventration may not be present to any significant extent. Impaired ventilation leads to the dominant complaint of dyspnea. As portions of the lung adjacent to the dysfunctional diaphragm display alveolar hypoventilation, regional vasoconstriction occurs, with relative ventilation/perfusion mismatch. Mild hypoxemia may be present, inciting compensatory hyperventilation and patient perception of shortness of breath. Orthopnea may also be present as the individual's abdominal organs displace lung volume in a supine position. For patients with both of these diagnoses, diaphragmatic plication may be an effective therapy in achieving symptom relief.
Diaphragmatic plication has been shown to have efficacy in symptomatic patients with eventration as well as diaphragmatic paralysis. A number of operative techniques have been described, including those that are transabdominal as well as transthoracic. While early reports detailed open procedures, minimally invasive operations have been highly favored in recent literature. Regardless of the surgical approach, there are several generally accepted operative indications for plication. Patients should be symptomatic; no intervention is necessary for those individuals who experience no respiratory compromise as a result of their condition. There should be significant paradoxical motion of the affected hemidiaphragm seen on the sniff test. For patients who have phrenic nerve paralysis after cardiac surgery, operative intervention should follow a period of observation (typically 1 year) if it is reasonably tolerated, as many of these paralyses are transient and improve with time. Finally, patients ought to be appropriate operative candidates. Benefits of plication are modest, and, as with all interventions, the risk–benefit ratio should be carefully weighed for each patient.

Traditionally, diaphragmatic plication has been described through a thoracotomy via the 8th intercostal space. The lateral and posterior portions of the diaphragm are gathered in a pleated approach with interrupted 0 sutures that are pledgeted (Fig. 26.9A). Sutures are placed at 1 cm intervals and brought from the central portion (medially) of the diaphragm out to the peripheral margin of the diaphragm laterally (Fig. 26.9B). Completion of the plication affords the patient a taut diaphragm that will overcome the phrenic nerve dysfunction on that side by reducing the position during peak inspiration.

The thoracosopic approach has also been described recently. For this approach a double-lumen tube is placed and the technical points are demonstrated in Figure 26.9C. The principles of the operation follow those of the open approach. This is certainly more challenging because of the steric issues encountered.

Our preferred approach to diaphragmatic plication is via laparoscopy. This approach works well for both left- and right-sided paralysis. We perform this procedure under general anesthesia with a single-lumen endotracheal tube. (Selective ventilation is not necessary.) Patients are placed in a supine position and secured to the operating table to allow for steep reverse Trendelenburg positioning during the procedure. Four 12-mm trocars are placed, with two in the midline and an additional two in the ipsilateral upper quadrant of the abdomen. Consequent to the pneumoperitoneum, the abnormal hemidiaphragm is displaced cranially. Electrocautery is used to make a small perforation in the dome, and the chest is entered. The resultant pneumothorax allows the hemidiaphragm to be pulled downward for plication.

For the plication, we use pledgeted nonabsorbable suture to place U-stitches into the diaphragm. The posterior portion is plicated first in an anteroposterior direction followed by a second plication line directed lateromedially, resulting in a final T-shaped plication (Fig. 26.10). In the process of performing the plication, the initial perforation at the dome is closed. We then place an 18F to 20F chest tube in the ipsilateral chest at the end of the procedure. Patients receive intense postoperative pulmonary toilet, and chest tubes are removed when drainage diminishes to less than 200 ml/day. Initial postoperative radiograph should demonstrate the plicated diaphragm at a lower position than the unaffected contralateral side. This will normalize with both diaphragms at the same level by 1-month follow-up. At 1 month postoperatively, both diaphragms
should be at the same level. While there are a number of additional methods described for diaphragmatic plication, our outcomes—with regard to symptom relief, hospital course, and postoperative complication—have been excellent with this strategy.

Central Nervous Diaphragmatic Failure

Though less common than phrenic nerve paralysis, diaphragmatic dysfunction may be secondary to central neurologic disorders, including high cervical spinal cord injuries and primary alveolar hypoventilation. While spinal cord injuries are due almost exclusively to trauma, or rarely occur after an ischemic event, primary alveolar hypoventilation is a congenital disorder. Patients with this diagnosis fail to manifest an appropriate autonomic response to hypercarbia and
hypoxia, secondary to abnormal receptors in the medulla oblongata. These individuals are at great risk of apneic events during sleep; during wakeful periods, they continue to breathe via conscious efforts. Diaphragmatic pacing may serve as a potentially useful therapy for these patients. Pacing may also be beneficial for individuals with cervical spine injuries, and is most useful for those above the C3 level, as the phrenic nerve remains intact. If C3–C5 nerve roots are involved, less benefit is derived from pacing, and if the injury is below C5, there is no benefit to phrenic nerve pacing.

In order to pace the diaphragm, an electrode must be placed in contact with the phrenic nerve. This may be accomplished via open cervical or thoracotomy approach, or, more recently, thorascopic approaches have been described, as well. Patients should not be paralyzed intraoperatively, so that stimulation of the nerve can be recognized. The electrode should ultimately be placed against the phrenic nerve adjacent to the mediastinum. This is connected to a subcutaneously placed receiving unit, which in turn communicates with an external pacemaker.

**Porous Diaphragm Syndromes**

Porous diaphragm syndromes are an uncommon and diverse group of diseases that result from a common anatomic etiology. That etiology is a diaphragmatic defect that affords the translocation of substances from the peritoneal cavity into the pleural space. The most common site of the defect is in the tendinous portion of the diaphragm. These defects may be congenital, but more often are acquired. Thoracic involvement tends to be more common on the right side.

Two of the most illustrative examples of these syndromes include Meigs syndrome and catamenial pneumothorax. In Meigs syndrome (fibroma or fibroma-like benign ovarian tumor, ascites, and pleural effusion), there is a clear relationship between the tumor, ascites, and pleural effusion. Surgical removal of the tumor treats the syndrome, and the thoracic surgeon is involved in management of the pleural effusion until resolution of the hydrothorax. In catamenial pneumothorax, patients present with a spontaneous pneumothorax that occurs at the start of a menstrual cycle. Prevailing evidence suggests that ectopic endometrial implants along the diaphragm cause perforations in the diaphragm leading to retrograde filling of the thoracic cavity with air from the fallopian tubes. Treatment involves thoracoscopy (or thoracotomy) with closure of the diaphragmatic defect, if it can be identified, and pleurodesis. Menstrual periods must be chemically ablated for several months before and after the procedure to avoid a high incidence of recurrence.

**Diaphragmatic Malignancies**

Infrequent in occurrence, the majority of primary diaphragmatic tumors are benign, with a number of described histologies. These include fibromas, lipomas, neurofibromas, schwannomas, and leiomyomas, as well as bronchial, echinococcal, mesothelial, and teratogenous cysts. Among malignant tumors of the diaphragm, fibrosarcomas and solitary fibrous tumors are the most common. Such primary lesions of the diaphragm may be discovered incidentally on chest radiography, and can be further characterized with MRI and/or CT imaging.

More common than primary diaphragmatic tumors, malignancies originating elsewhere may involve the diaphragm by direct extension. This may be seen with thoracic malignancies, such as bronchogenic carcinoma, mesothelioma, and tumors of the chest wall or mediastinum, as well as in association with tumors originating from abdominal sites, such as the esophagus, stomach, or liver.

Masses of the diaphragm—both benign and malignant—should be resected. Those which are malignant should be removed with a wide margin of normal tissue, regardless of the size of the resultant defect. Use of prostheses or muscle flaps may be necessary to deal with large tissue defects. However, if a significant defect is repaired and the resultant diaphragm seems likely to have impaired phrenic nerve function, then the repair should be taut enough to avoid paradoxical motion upon inspiration.

**Diaphragmatic Flap**

While uncommonly employed as such, the diaphragm may be used as a pedicled flap for tissue coverage when needed in the chest. Specific applications may include reinforcement of bronchial stumps, as well as coverage of bronchopleural fistulas, esophageal leaks, and esophageal perforations. Although there are other options available for vascularized pedicled flaps, the diaphragmatic flap is a useful technique to have in one’s surgical armamentarium.

In order to harvest a diaphragmatic flap, one should approach the diaphragm from the thoracic operative field. After initially incising the diaphragm, a light source may be introduced to the abdomen. Transillumination is particularly useful in identifying the phrenic artery in order to maintain the vascular supply of the pedicled flap. The diaphragm is next divided, beginning posteriorly and continuing anteriorly. In order to optimize vascularity, the width of the flap should be about...
Thoracic surgeons do not spend a lot of time thinking about the diaphragm unless problems occur. Neoplasms are exceedingly rare yet the diaphragm certainly can be involved by malignancies from adjacent organs and partial resection may be required to completely resect a tumor from, for instance, the lower lobe of lung. In addition, for those patients with malignant pleural mesothelioma who undergo extrapleural pneumonectomy, resection of the diaphragm with patch reconstruction is a key component of the procedure.

Diaphragmatic paralysis from whatever cause usually results in significant dyspnea on exertion initially; yet, with time, the symptoms often improve to the extent that surgical correction is rarely required. Likely this is not due to restoration of function of the paralyzed hemidiaphragm but simply the result of a physiologic accommodation. In our experience evagination of the diaphragm rarely results in symptoms to such an extent that plication is necessary. Differentiating evagination from paralysis sometimes may be difficult but the distinguishing feature is significant paradoxical motion of the paralyzed diaphragm seen during the sniff test. In the patient with a paralyzed diaphragm plication will likely contribute little to symptom relief unless significant paradox is demonstrated.

Diaphragmatic pacing has been performed in a few specialized centers and the indications for the procedure are few, the main one being central hypoventilation syndrome. For diaphragm pacing to be useful the phrenic nerve must be intact and thus the procedure is not indicated for those with phrenic nerve injury. There has been some work done in reinnervating the diaphragm using intercostal nerve anastomosed to the phrenic nerve.

The porous diaphragm syndromes present unique challenges, each of which must be addressed on an individual basis. The exact cause of catamenial pneumothorax remains elusive since rarely is a specific lesion seen at the time of operation. Unless the monthly menstrual cycle is chemically interrupted, recurrence is highly likely with the onset of the first period following surgical repair and pleurodesis. Patients who present with ascites with persistent leakage into the chest also present difficult management problems as rarely is a specific communication found. Pleurodesis usually fails to resolve the problem and resolution usually only is achieved when the specific cause of the ascites is addressed.

The authors have done a superb job in summarizing all of the major issues related to the diaphragm that are of importance to the surgeon.

---

**Fig. 26.11.** Technique for harvesting a diaphragmatic flap.
Chylothorax is the abnormal accumulation of fluid from the lymphatic system within the pleural space. Chyle is not only composed mainly of the lymphatic drainage from the intestine but also includes lymph from the lungs, liver, abdominal wall, and the extremities. The amount of lymph originating from the extremities as a component of chyle is negligible under normal circumstances. Chylothorax may be either congenital or acquired (Table 27.1). Congenital chylothorax is thought to occur either secondary to disruption of the thoracic duct during delivery or to congenital anatomic abnormalities of the duct, such as atresias. Acquired chylothorax can arise from multiple causes. Disruption of the thoracic duct may occur due to blunt thoracic or cervical trauma. Occasionally, the duct is injured in penetrating thoracic trauma, although the posterior location of the duct makes this form of injury quite uncommon. The thoracic duct may be lacerated during placement of left subclavian venous catheter, however, far more commonly is injury to the duct or its tributaries, occurring during thoracic operations. Chylothorax has been estimated to occur after 0.25% to 0.50% of all intrathoracic operations and has been described after nearly every type of thoracic surgical procedure but appears to be more common following cardiac procedures requiring considerable mediastinal dissection at the base of the heart or after esophagectomy.

Mediastinal neoplasms are responsible for the majority of chylothoraces that develop spontaneously in adult patients. Most of these are secondary to obstruction of lymphatic pathways from mediastinal lymphomas. Infections are an uncommon cause of chylothorax in the United States, but tuberculous lymphadenitis is a more common cause in many other countries. Miscellaneous causes for chylothorax include thrombosis of the subclavian vein or superior vena cava (SVC), usually secondary to long-dwelling intravenous catheters, child abuse, and pulmonary lymphangiomatosis (Table 27.1).

**ANATOMY**

The thoracic duct is the largest lymphatic channel in the body. It conveys the majority of the lymph within the body into the circulatory system. The duct arises embryologically as paired channels with numerous crossing anastomoses. In most instances, the paired structures fuse to form a singular vascular channel with the right duct persisting in the lower thorax and the left persisting in the upper chest (Fig. 27.1). Although up to 50% of individuals may have anomalous patterns of thoracic duct anatomy, in its most classic anatomic position the duct arises from the cisterna chyli anterior to the first or second lumbar vertebral body. The duct runs cephalad from the cisterna along the right side of the aorta and enters the chest through the aortic hiatus. The duct ascends in the right thorax, medial to the azygos vein and posterior to the esophagus. At the level of the fourth or fifth thoracic vertebra, the duct crosses anterior to the vertebral body and behind the esophagus to become a left-sided structure, dorsal to the aortic arch. The duct passes through the thoracic inlet posterior and to the left of the esophagus and forms an arch that rises 3 to 4 cm above the clavicle to the level of the sixth or seventh cervical vertebrae. It crosses anterior to the subclavian artery and the thyrocervical trunk as it extends laterally and terminates by opening into the angle of the left subclavian and the internal jugular veins (Fig. 27.2). A bicuspid valve at the lymphaticovenous junction prevents the reflux of blood into the duct at this junction. The duct is 3 to 5 mm in diameter at its origin in an adult, but its caliber diminishes in the mid-thorax to dilate again just proximal to its venous termination. The duct receives numerous lymphatic tributaries from the thoracic wall as it ascends through the chest, and there are multiple lymphaticovenous anastomoses between the duct and the azygos and intercostal veins.

Riquet described two major thoracic duct tributaries from the heart. The right efferent trunk primarily drains lymph from the right ventricle and ascends between the aorta and pulmonary artery, connecting to the thoracic duct high in the left chest. The left efferent trunk drains lymph primarily from the left ventricle and ascends behind the pulmonary artery, usually connecting with the azygos vein in the right chest. Injury to the right efferent trunk may account for many cases of chylothorax or chylopericardium after cardiac surgery.

Although this represents the most common anatomic configuration of the duct, there are numerous variations that may be of considerable surgical significance. The most common variation in anatomy is a duplicate duct, occasionally at the lower thoracic, but more commonly at the cervical level. The level at which the duct crosses the vertebral column may also be variable.

**PHYSIOLOGY**

There are multiple valves throughout the length of the thoracic duct, particularly in the cephalic end, that ensure unidirectional flow. The wall of the thoracic duct contains smooth muscle cells with an intrinsic contraction interval of 10 to 15 seconds. Movement of chyle through the thoracic duct is modulated primarily by the intrinsic contraction of the duct wall and the pressure gradient between the abdomen and thorax. The rate of lymph formation from the intestine and liver also affects the rate of flow through the duct. Flow through the thoracic duct varies between 0.38 and 3.9 ml/min.

The function of the thoracic duct is to transport ingested fat and lymphatic fluid from the abdominal viscera and lower body into the venous circulation. Approximately 60% to 70% of all ingested fat is absorbed by the intestinal lymphatics and transported by the thoracic duct. Fatty acids containing <10 carbon atoms are absorbed directly into the portal venous system, whereas...
larger fats are formed into chylomicrons and transported into the lymphatics. The thoracic duct is also the main pathway for return of extravascular plasma proteins and lymphocytes to the vascular space. Prolonged loss of thoracic duct lymph can lead to fat and protein malnutrition as well as to immunocompromise secondary to loss of T lymphocytes.

**DIAGNOSIS**

The diagnosis of chylothorax is suspected with the development of a pleural effusion in certain high-risk clinical settings, such as after esophagectomy. The diagnosis is confirmed by examination of the pleural fluid obtained by thoracentesis. In an individual consuming a normal diet, the diagnosis is usually quite evident, with a milky appearance to the fluid. Often, however, the patient has not received normal fats enterally before the development of the chylothorax, and the fluid in this clinical setting has the appearance of serum. Chemical analysis of the fluid reveals elevated triglyceride and total protein levels (Table 27.2). Cell counts reveal a marked predominance of lymphocytes, with numbers ranging from 400 to 7000/ml. Chronic pleural effusions secondary to tumors or infections may occasionally appear milky because of the accumulation of cholesterol in the fluid. This so-called pseudochylothorax can be differentiated from true chylothorax by the determination of the triglyceride level in the effusion. Most chylous effusions have a cholesterol/triglyceride ratio of <1, whereas nonchylous effusions have a ratio of >1. Pleural fluid with a triglyceride level of >110 mg/dl has a 99% chance of being chyle. If the triglyceride level is <50 mg/dl, the probability of a chylous effusion is only 5%.

The thoracic duct may be visualized by standard lymphangiograms or by nuclear scintigraphy. Often these studies will demonstrate the anatomy of the duct and the level of the lymphatic leakage. They are rarely helpful, however, in the management of these patients and should not be considered a routine part of their evaluation.

**CLINICAL PRESENTATION**

Chylothorax primarily causes symptoms of respiratory insufficiency as the volume of the effusion gradually increases. Most cases of chylothorax are slow in their progression, and symptoms do not occur for several days to several weeks after the initial injury to the duct. Rapid accumulation of chyle with the production of severe respiratory symptoms is uncommon but is occasionally encountered after complete transection of the duct by traumatic or surgical injury. Chyle itself is bacteriostatic, probably because of its high fatty acid content, and symptoms of pleural infection are uncommon. Patients with longstanding chylothorax with loss of significant volumes of chyle often become hypoproteinemic. These patients also often develop lymphopenia from the loss of T lymphocytes in the chyle and may

In fact, malnutrition and infection account for the majority of deaths after the development of a chylothorax.

**MANAGEMENT**

The control of chylothorax is thought to occur with the formation of pleural adhesions in the region of the chylous leak, thus preventing the flow of lymph from the thoracic duct or its branches. The management of patients with confirmed chylothorax, therefore, begins with attempts to completely drain the lymphatic fluid from the chest. In some cases, this may be accomplished by thoracentesis, whereas in most patients, with more rapid fluid accumulation, a tube thoracostomy is required. Measures are then instituted to reduce total thoracic duct lymphatic flow, initially using an oral diet containing fats primarily in the form of medium-chain triglycerides, which are absorbed directly into the portal venous system. Patients in whom significant lymphatic flow persists may require total elimination of enteral nutrition, with the institution of intravenous alimentation.

Several clinical reports have suggested that the use of somatostatin or its longer acting synthetic analog octreotide may stop persistent chylous accumulation. The effect of somatostatin on thoracic duct flow is probably secondary to its reduction of splanchnic blood flow and its reduction of intestinal fat absorption, reducing chylomicron synthesis. Somatostatin has generally been administered as an intravenous infusion, using 250 µg/h in adults and 3.5 to 10 µg/kg/h in children. The dose may be increased in stepwise manner to maximal response. Octreotide has generally been administered subcutaneously at doses of 100 µg twice or thrice daily for adults and 10 to 40 µg/kg per day in children (Table 27.3). Children and diabetic adults should be monitored for hyperglycemia or hypoglycemia, and adults are occasionally noted to have cardiac arrhythmias. The safety profile of these drugs, however, appears excellent, and they should be used early in patients with persistent chylous effusions to attempt to avoid protein and fat loss.

The length of time that it is reasonable to persist with conservative therapy is somewhat controversial and depends on the cause of the chylothorax and the volume of lymphatic loss. Some authors suggest intervention in cases of traumatic chylothorax when the daily loss of chyle exceeds 1,500 ml in adults or 100 ml per year of age...
The mortality for patients with chylothorax was approximately 50% until Lampson described mediastinal ligation of the thoracic duct in 1948. This procedure remains the most commonly used operation for persistent chylothorax, although several alternative procedures have been developed in recent years. In patients with unilateral chyloous effusions, the chest should be opened on the ipsilateral side, whereas in cases of bilateral effusion, the right chest should be chosen initially. Many authors recommend instillation of 100 to 200 ml of olive oil or cream into the stomach several hours before the operation to increase the fat content of the thoracic lymph and make the area of leakage from the duct itself more easily identifiable. After the induction of general anesthesia with orotracheal intubation, the patient is placed in a full lateral decubitus position. A posterolateral thoracotomy is performed, and the chest is entered through the seventh or eighth intercostal space. If the chylothorax has developed after a previous thoracotomy, the original incision is opened. The mediastinal tissues are examined carefully for the evidence of chylous leak. If such an area is identified, this region should be obliterated with nonabsorbable sutures, occasionally using polytetrafluoroethylene (Teflon) pledgets to compress larger areas of tissue. Whether or not a specific area of leakage is identified and controlled, the main thoracic duct should be ligated as it enters the chest through the aortic hiatus. To accomplish this, the esophagus is encircled and retracted anteriorly, and the tissues between the azygos vein and the descending aorta just cephalad to the aortic hiatus are ligated with nonabsorbable sutures (Fig. 27.3). In most cases, the actual thoracic duct may be identified in this area and ligation performed, whereas in other cases mass ligation of the tissues in this area is accomplished, without direct identification of the duct itself. The chest is closed in layers with a single large chest tube connected to a water seal. A retropleural approach to the thoracic duct has been described. The patient is placed under general anesthesia and positioned prone, and a segment of the right posterior eighth rib is resected after the periosteum is stripped. The posterior mediastinal pleura is dissected bluntly from the chest wall in this region, and the thoracic duct is identified medial to the azygos vein. The duct is obliterated with nonabsorbable suture material, and the incision is closed in layers without drainage.

Patients in whom the source of the chylothorax is suspected to be relatively localized, such as patients developing a chylous effusion after blunt or penetrating thoracic trauma, may benefit by thoracoscopic control of the lymphatic leak. Although the procedure may be performed under local anesthesia in these patients, the use of general anesthesia with unilateral ventilation greatly enhances the exposure of the mediastinum. The patient is placed in a full lateral decubitus position or rolled

slightly forward to facilitate exposure of the posterior mediastinum. The initial trocar for the thoracoscope is placed in the sixth intercostal space in the mid-axillary line. A second trocar is placed posteriorly in the same or adjacent interspace (Fig. 27.4). The residual pleural lymph is aspirated, and the pleura overlying the posterior mediastinum is carefully examined from the level of the inferior pulmonary ligament to the innominate vein. In some cases, a defect in the parietal pleura will be discovered with lymphatic leakage through this region. We have preferred to use metallic clips on this tissue to obliterate the leak, although others have used direct suture ligation (Fig. 27.5). After the pleural leak is controlled in this region, the entire area is flooded with fibrin glue to form a seal over the parietal pleura. In most cases, the inferior pulmonary ligament is then divided with the electrocautery, and the thoracic duct is clipped or ligated at the level of the aortic hiatus. A single chest tube is placed through one of the trocar tracks while the other trocar sites are closed with subcuticular sutures.

If the origin of the chylous effusion is suspected to be more diffuse, such as in those patients who have undergone thoracic surgery or in patients with lymphangiomatosis or SVC thrombosis, the placement of a pleuropertitoneal shunt may be the best treatment strategy. In choosing to use a pleuropertitoneal shunt, the surgeon must decide between an internalized system, which is completely buried under the skin, and an exteriorized system, which leaves the pumping chamber exposed. The internalized system has the advantage of not requiring any maintenance of the catheter entrance or exit sites, but it does require a responsible patient or parent who is willing to compress the chamber as frequently as necessary in spite of some potential discomfort. The exteriorized system has proven quite helpful in small infants who may not tolerate chest wall compression well and has advantages in obese patients in whom the internalized chamber may be difficult to localize. This system facilitates the control of high-volume chylous leaks that require frequent pump compression. The disadvantage of the exteriorized system is the need for cleaning and dressing the catheter exit sites and the potential for infection through these sites.

Both the internalized and externalized systems may be placed under local anesthesia, although the use of general anesthesia facilitates the procedure. It is helpful in placing either of these systems to have some residual chyle within the chest at the time of the operation. This allows the surgeon to test the patency of the shunt system. If a chest tube is already in place, it may be clamped the night before the procedure to allow accumulation of chyle. The patient is placed in the supine position with the affected chest elevated 30 to 45 degrees with a wedge. The entire chest and abdomen of the affected side are prepared and draped. The pleuropertitoneal shunt system is placed on the body surface to determine the optimal position of the shunt and the incisions. It is helpful to mark the incisions with a skin pencil at this time. The pumping chamber for the internalized system should be placed in a subcutaneous pocket overlying the lower ribs of the anterolateral chest wall. The pleural catheter should be directed as far posteriorly as possible to allow optimal-dependent drainage. A 2-cm skin incision is made just caudal to the proposed intercostal entrance of the pleural catheter. A generous subcutaneous pocket is dissected caudal from...
this area over the lower ribs. A 2-cm transverse incision is made overlying the anterior rectus sheath midway between the umbilicus and the xiphoid process (Fig. 27.6). The anterior rectus sheath is divided transversely, and the fibers of the rectus muscle are separated to expose the posterior rectus sheath and peritoneum. Two concentric purse-string sutures of 4-0 polypropylene (Prolene) are placed in the posterior rectus sheath. The pleuropertitoneal shunt system is filled with sterile saline by compressing the pumping chamber while the entire system is under fluid. Careful attention must be paid to orienting the pumping chamber in the proper direction because there are two unidirectional valves within the chamber.

The pleural catheter is trimmed to appropriate length and placed across the intercostal space in tangential manner. This is the most critical portion of the operation, and care must be taken not to kink the catheter as it crosses the chest wall. A long clamp is then passed from the lower incision to the upper incision, through the subcutaneous pocket, and the distal catheter and pumping chamber are drawn into the pocket by traction (Fig. 27.7). The pumping chamber must be seated well within the pocket to ensure that neither of the incisions is directly over the compression chamber. Patency of the system is confirmed by repeatedly compressing the pumping chamber and observing for free flow of chyle through the distal tubing (Fig. 27.8). The peritoneal catheter is trimmed to appropriate length, and the posterior rectus fascia and peritoneum are opened within the purse-string sutures and the catheter passed into the abdominal cavity. Both purse strings are tied securely around the catheter. The patency of the system is checked once again by repeatedly compressing the pumping chamber to ensure free flow of fluid. The two incisions are closed with subcutaneous and subcuticular absorbable sutures.

Planning for an exteriorized system starts as for the internalized system. The shunt is placed on the body surface to determine the best position for the incisions. Subcutaneous tunnels of approximately 6 to 10 cm in length are made for proximal and distal tubing. A 1-cm incision is made overlying the interspace through which the thoracic catheter will be placed, and a 2-cm incision is made overlying the anterior rectus sheath just above the level of the umbilicus. The thoracic catheter is drawn through the subcutaneous tunnel by passing a clamp in a caudad direction from the interspace incision. The Teflon cuff surrounding the catheter is placed at the level of the thoracic insertion (Fig. 27.9). The abdominal catheter is drawn through the subcutaneous tunnel by passing a clamp cranially from the rectus incision, and the cuff is positioned to lie at the level of the peritoneum. Two concentric purse-string sutures are placed through the posterior rectus fascia and peritoneum, as for the insertion of the internalized system, and the peritoneal catheter is inserted (Fig. 27.10). The two purse-string sutures are tied, and each is sutured to the Teflon cuff of the abdominal catheter. The thoracic cuff is not sutured to the thoracic fascia. The incisions are closed in layers after the system is tested by compressing the exteriorized pumping chamber (Fig. 27.11). The catheters are sutured to the skin at the exit sites, and sterile dressings are applied.
Postoperatively, a schedule of pump compression is established that will allow complete evacuation of chyle from the thorax. An estimate of the frequency of compression necessary can be made by identifying the preoperative volume of lymphatic leakage and estimating that each compression of the chamber pumps approximately 2 ml of chyle from the chest to the abdomen. Usually, the patients are asked to compress the chamber for a certain number of times, 4 times a day. With the exteriorized chamber, the patient can easily tell when the chest is empty because the chamber will not fill with chyle after compression.

When the flow of lymph through the pleuroperitoneal shunt has diminished to a minimum, the patient is instructed not to pump the chamber for an interval of 2 weeks, after which a chest radiograph is obtained to be certain that there is no reaccumulation of fluid. If the chest is dry, the shunt is removed by simply withdrawing the pleural catheter. The abdominal catheter is dissected out, and the entrance through the posterior rectus fascia is closed with interrupted absorbable sutures to prevent visceral herniation.

**THORACIC DUCT EMBOLIZATION**

The rationale of thoracic duct embolization (TDE) was initially conceptualized and tested by Dr. Constantine Cope from the University of Pennsylvania based on the underlying assumption that the ability to visualize the lymphatic system and TD abnormality using lymphangiogram could increase the treatment success and a minimally invasive percutaneous approach could decrease morbidity and mortality.

Over the years, pedal lymphangiogram has proved to be the major obstacle for wider acceptance of TDE. Traditional pedal lymphangiography is both time-consuming and technically challenging, and requires specialized equipment that is not readily available. The recent development of the intranodal lymphangiogram opened the door to more widespread use of TDE from specialized academic centers to the community hospitals. Based on a simple ultrasound-guided puncture of the groin lymph nodes, this procedure is within basic skills of any interventionalist practicing ultrasound-guided procedures. Intranodal lymphangiography has been described as a technically less challenging alternative to conventional pedal lymphangiography.
Chapter 27: The Thoracic Duct and the Management of Chylothorax

The feasibility of using intranodal lymphangiography for TDE has been well demonstrated. Using intranodal lymphangiogram, the abdominal-pelvic lymphatics, cisterna chyli, and thoracic duct may be visualized and subsequently the thoracic duct successfully accessed and embolized. This technique also significantly reduces the embolization time, mainly due to more rapid catheterization of the lymphatic system and faster transit time between the initiation of the lipiodol injection and opacification of the TD. Overall, intranodal lymphangiography for TDE appears to be easier, safer, and faster than the older method of pedal lymphangiography.

**Thoracic Duct Embolization Description of the Technique**

After the cisterna chyli and/or its tributaries are visualized following a intranodal lymphangiogram, the lymphatic system is accessed transabdominally using a 21- to 22-G needle. To prevent the leakage of chyle from cisternal chyli, the access to the lymphatic system is performed through the lymphatic feeders below the cisterna chyli (Fig. 27.14). Using this access, a stiff 0.018 inch wire (V-18, Boston Scientific, Natick, MA) is advanced into the TD, followed by a 3-F microcatheter (Rapidtransit, Cordis Hialeah, FL).

Contrast is then injected through the catheter in an attempt to demonstrate the origin of the chyle leak. In traumatic chylothorax, the cause of the leak is most often a tear of the thoracic duct or leakage from a TD branch (Fig. 27.15A and 27.15B). In idiopathic chylothorax, the cause of the chylothorax frequently is occlusion of the upper part of the thoracic duct (Fig. 27.16).

If the TD appears to be normal and there is an unobstructed flow of the contrast into the left subclavian vein, the duct should not be embolized. In this situation, the diagnosis of chylothorax has to be questioned. To confirm the diagnosis, a food challenge test using a bolus of cream has to be performed and the level of the triglycerides in the effusion is measured. If the diagnosis is confirmed, other causes of the chylothorax have to be suspected, such as chylous ascites or a lymphatic malformation.

After the cause of the leak is identified, embolization of the thoracic duct is performed below the origin of the leak (Fig. 27.17). If the leak is identified as coming from a branch of the TD, selective catheterization of the branch can be attempted. The embolization is performed

---

**Intranodal Lymphangiography**

In this technique, an inguinal lymph node is directly accessed with a 25-gauge spinal needle (BD Medical, Franklin Lakes, NJ) under ultrasound guidance with the needle tip positioned in the hilum of the node (Fig. 27.12). Subsequently, an oil-based contrast agent (Ethiodol; Savage Laboratories, Melville, NY) is injected by hand at a rate of about 1 to 2 ml per 5 minutes. If successful, immediate opacification of the lymphatic vessels is observed under fluoroscopy (Fig. 27.13). A total volume of approximately 6 ml of contrast is injected into a lymph node in each groin to opacify the abdominal and pelvic lymphatics in an adult. To further propel the advance of the contrast in the lymphatic system, the injection of lipiodol is followed by injection of saline (“saline flash”). The injection of saline into lymph nodes is painful for the patient and for that reason intravenous sedation is recommended.

---

**Fig. 27.10.** The catheters are placed with the polyethylene terephthalate (Dacron) cuffs at the level of the intercostal muscles and the posterior rectus sheath (inset). The anterior rectus sheath is opened (1). The rectus muscle is split in the direction of its fibers (2). The posterior rectus sheath (3) and peritoneum are opened. The catheter is inserted and secured with two purse string sutures (4) one through the peritoneal and Dacron cuff, the other through the posterior rectus sheath and the Dacron cuff with care to avoid damage to the shunt.
using a combination of embolization coils and NBCA glue (Truefill, Cordis Hialeah, FL). If a leak is suspected from multiple small collaterals, then embolization with NBCA glue only can be performed.

In case TD catheterization is technically unsuccessful, TD needle disruption has been described. Using this technique, the retroperitoneal lymphatics are disrupted using a "twiddling motion with the needle." The idea is that traumatic disruption of the lymphatic vessels results in controlled bleeding into lymphatic vessels and the blood clots and/or local inflammation would close the leak.

Given the technical difficulty of the procedure, there remains interest in optimizing performance by improving guidance to aid in puncturing the thoracic duct. Recently, combining MRI with fluoroscopy to guide access to the thoracic duct has been described.

**THORACIC DUCT EMBOLIZATION OF TRAUMATIC CHYLOTHORAX**

Iatrogenic injury of the TD or its branches during thoracic, cardiac, or neck operation remains the most frequent cause of traumatic chylothorax. Traumatic chylous ascites also may present as chylothorax. The negative pressure developed in the chest during inspiration causes the chyle to migrate from the abdomen into the pleural space through pores in the diaphragm.

Chylothorax following a surgical procedure usually presents within the first 2 weeks following operation. The incidence of chylothorax complicating pulmonary resections can be as high as 4%, and recent report suggests that the incidence may be rising given the increased frequency of extensive resections and lymph node dissections performed by thoracic surgeons. Morbidity and mortality resulting from a chylothorax are significant. Chylothorax following esophagectomy is associated with a statistically significant increase in 30-day major complications (85% vs. 46%; \( p < 0.001 \)) and death (17.7% vs. 3.9%; \( p < 0.001 \)) when compared with patients with no chylothorax.

Overall, conservative therapy only resolves the chylothorax in <50% of cases with a reported mortality of 50% to 75%. Success of thoracic duct ligation in treating chylothorax following esophagectomy approaches 67%. Although these results are promising, the operative risk and morbidity, when compared with the safety and improved outcomes associated with TDE make it, at least in our hands, the preferred alternative to surgical ligation. The growing experience with TDE and the advent of intranodal lymphangiography supports its use as first-line treatment for traumatic chylothorax.

The largest series of TDE in treating traumatic chylous effusions detailed results in 109 patients. In 73 of 109 cases, the TD was catheterized, and TDE with endovascular coils and/or NBCA glue was performed in 71 of 73 patients. The leak resolved in 64 of 71 (90%) of these patients. In 18 of the 33 cases in which TD catheterization was unsuccessful, needle interruption of the thoracic duct below the diaphragm was attempted and resulted in resolution of the chylothorax in 72% of patients. Overall success based on intent to treat for the entire series was 71%. In 20 patients who had failed previous surgical ligation, embolization or interruption was attempted in 17 and was successful in 15 (88%) demonstrating the utility of TDE even after failed surgical intervention. The most common causes of operative TD ligation failure were “missed TD” (Fig. 27.18), incomplete ligation of the TD (Fig. 27.19), or leak from the "stump" of the ligated duct (Fig. 27.20). In some cases, persistent chylothorax was present in spite of lymphangiographic demonstration of complete ligation (Fig. 27.21). In these cases, injection of the cisterna chyle with NBCA glue completely alleviated the chylothorax. There were 3 (3%) minor complications observed in this study.

In the pediatric population, chylothorax is most commonly observed after cardiac surgery and has a reported incidence of 2% to 5%. TDE in the pediatric population is more challenging due to the small size of the lymphatic vessels. Generally, the technique of TDE in children is similar to adult with
Chapter 27: The Thoracic Duct and the Management of Chylothorax

In this quite common situation, the opacification of the cisterna chyli and TD happens within minutes.

one exception: in children with right-to-left shunt use of an oil-based contrast agent (lipiodol) has the potential to result in systemic fat embolism. Fortunately, it is possible to use water-based contrast in these patients.

THORACIC DUCT EMBOLIZATION FOR NONTRAUMATIC CHYLOTHORAX

Nontraumatic chylothorax is a relatively rare condition in which the leak develops without any precipitating traumatic event. The causes of the nontraumatic chylothorax include malignancy, congenital abnormalities, systemic diseases (e.g., SLE and Behcet disease), infection (e.g., tuberculosis), and an idiopathic group where seemingly no cause can be determined.

These cases present considerable diagnostic and therapeutic challenges when compared with those with a traumatic chylothorax. Generally, there are three types of underlying anatomical abnormalities that may result in chylothorax: (1) chylous ascites that presents as chylothorax; (2) occlusion of the upper part of the TD with subsequent development of the pleural collateralization and chyle leak; and (3) chylothorax associated with lymphatic malformation.

Recently, experience in 34 patients undergoing TDE for nontraumatic chyloous effusions was reported. Thoracic duct catheterization and embolization were technically successful in 24 of 34 patients (70.6%). Overall, the clinical success rate evaluated based on “intention to treat” criteria was 53% (N = 18 of 34). In the group in which the TDE was technically successful (N = 24), the clinical success rate was 67.7% (N = 16). Interestingly, the clinical success rate was varied based on the lymphangiographic pattern. The greatest clinical success (88%) occurred in patients who were found to have an occlusion of the thoracic duct with multiple mediastinal collaterals and complete obstruction of passage of contrast from the thoracic duct into the subclavian vein (Fig. 27.16). The lowest success rate (16%) was observed in patients with thoracic duct on lymphangiography. It is possible that in these patients the sources are intestinal lymphatics, which communicated directly with the pleural space. This group does indeed presents significant challenges.

Over the years, an algorithm has been developed for the evaluation and treatment of these patients. If free fluid in the abdomen is identified on cross-sectional imaging, chylous ascites and passage of the chyle from the abdomen into the chest are suspected. In this case, sampling of the abdominal fluid and testing it for chyle are recommended. As mentioned earlier, the diaphragmatic openings that result in free communication of the fluid between abdomen and chest have been described. In these cases, the placement of the peritoneal-venous shunt is indicated as primary treatment. If chylous ascites is not identified, we perform heavily weighted T2 MR imaging of the chest and abdomen to define the anatomy of the thoracic duct to exclude lymphatic malformation and attempt to identify lymphatic malformations which could be culprit for chyle leak (Fig. 27.22).

To examine the patency of the thoracic duct, we perform an intranodal
Section I: General Thoracic Surgery

Fig. 27.14. Digital X-ray demonstrating the planning for the access of the lymphatic system. The tip of the hemostat (white arrowhead) marks the skin entry site through the lumbar lymphatic vessel (black arrowhead) that feed into cisterna chyli (black arrow).

A lymphangiogram. In cases where the TD is occluded and multiple collaterals are identified (Fig. 27.16), TDE is performed. In those situations where the TD is patent and there is free flow of the contrast into subclavian vein, TDE should be avoided. If lymphatic malformation is identified on the MRI or lymphangiogram, sclerotherapy and/or direct injection of the lymphatic malformations with embolization material is performed.

Fig. 27.15. (A) Injection with the contrast of the distal part of the TD through the microcatheter (white arrow) demonstrating the leak (white arrowhead) in patient with chylous leak after neck surgery. (B) Injection with contrast of the proximal part of TD through the catheter (black arrowhead) demonstrating the leak from the branch of the TD (black arrow). Surgical clip at the leakage point is noted. The surgeon saw the leak during the operation and unsuccessfully attempted to close it.

LOW TERM OUTCOME OF THORACIC DUCT EMBOLIZATION

With the growing experience with TDE to treat traumatic and nontraumatic chylous effusions, late term complications of the procedure, although rare, are now being recognized. Occlusion of the TD and redistribution of the significant fluid flow (2 to 3 l/day) can potentially result in long-term sequelae such as lymphedema, chylous ascites, and protein-losing enteropathy. A recent case report described an incident of chylous ascites occurring in a patient with a chylothorax who had a failed attempt at

Fig. 27.21. Fluoroscopic image of the injection of the contrast into cisterna chyli through microcatheter (white arrowhead). There is a complete obstruction of the flow by successful TD ligation using surgical clips (white arrow). Injection of the NBCA glue into cisterna chyli stopped the leak.

Fig. 27.22. Heavily weighted T2 MR image of the abdomen and chest. There is a high signal in the mid-abdomen corresponding to the multiple lymphatic malformations (arrows). Left pleural and pericardial effusions are noted.

cannulating the thoracic duct. This complication had not been observed in prior studies of TDE, which included cases of failed thoracic duct cannulation. In a long-term follow-up of patients who underwent TDE, chronic leg swelling and chronic diarrhea are complications that have been thought to be “probably related” to the procedure. These potential complications should be part of informed consent for the procedure.

The results of all of these invasive procedures for chylothorax are excellent. Sporadic case reports suggest that thoracic duct ligation is successful in controlling the chylous leak in approximately 85% of patients. Murphy indicated that pleuroperitoneal shunts are successful in 100% of patients with chylothorax after cardiac surgery and in 75% of patients with chylothorax secondary to caval obstruction. The success of thorascoscopic control of chylothorax appears comparable to that of these other procedures. Percutaneous techniques appear to be successful in approximately 70% of patients. Occasionally, a patient with diffuse lymphatic leak, such as a patient with caval obstruction or lymphangiomatosis, will fail to respond to these procedures. In these patients, a pleurodesis on the affected side will virtually always
control the chylous leak. This may be performed by thoracoscopy, using either pleural abrasion or talc pleurodesis, or by an open pleurectomy. TDE may prove to be the treatment of choice for chylothorax regardless of etiology due to its higher success rate and lesser morbidity. Over the past several years, the cumulative experience with TDE has increased significantly and the advent of intranodal lymphangiography offers the promise of increasing its use as the first-line therapy for chylothorax.

It is important to recognize that the development of chylothorax is not a benign condition. Treatment should be prompt and aggressive to minimize loss of protein, fats, and lymphocytes. The effusion must be drained, and the patient should be placed on a medium-chain triglyceride diet or total parenteral nutritional management. Somatostatin or octreotide should be instituted in those patients with drainage persisting for more than 3 days, and surgical therapy should be contemplated for effusions lasting 7 to 10 days. The choice of surgical procedure for the treatment of refractory chylothorax is determined by the experience of the surgeon and the cause of the chylothorax. Patients with direct injury to the duct from blunt or penetrating chest trauma may be the best candidates for posterolateral thoracotomy and direct control of the chylous leak as well as ligation of the main trunk of the thoracic duct. Patients with chylothorax arising secondary to thoracic surgical procedures in whom reexploration may be difficult or prohibitively stressful may be excellent candidates for the placement of a pleuroperitoneal shunt or percutaneous techniques, which may be performed under local anesthesia. Patients with long-standing and loculated chylothorax may benefit from thoracoscopic control, which enables the surgeon to disrupt the multiple loculations within the pleural space while controlling the leak of chyle.

**SUGGESTED READINGS**

And I thought I knew a lot about chylothorax. The authors have written an absolutely superb chapter that should be mandatory reading for all thoracic surgical residents as well as practicing cardiothoracic surgeons. I am including even those surgeons who limit their practice to adult cardiac surgery because chylothorax rears its ugly head on occasion following cardiac surgical procedures not to mention how often it is seen following surgery for congenital heart disease. I would submit that it is far easier to avoid a problem with the thoracic duct than to fix a problem with the duct, not to mention the morbidity that results from a chyle leak. Should a chylothorax occur, however, the surgeon should be familiar with the problem and the potential solutions because time is of the essence.

I have not had any personal experience with somatostatin or octreotide in managing chylothorax, but other than the expense, either of these agents might be tried early in the course of a chylothorax especially if the patient is draining <500 ml/day. Having waited too long to ligate the thoracic duct on at least one patient, I now wait no longer than 7 days to intervene if the leak does not stop with conservative measures. The morbidity of hypoalbuminemia and immunosuppression in an early postoperative patient is simply too great to take any chances. We have been the major proponents of percutaneous techniques for sealing the duct, and the procedure is well described in this chapter. The advent of intranodal lymphangiography should make thoracic duct embolization much more accessible as no longer is pedal lymphangiography, a lost art, required. If the cisterna and its tributaries can be visualized, there is a high likelihood of successful embolization with the resolution of the chylothorax thus saving the patient a surgical procedure. One can make a rather convincing argument that an attempt at thoracic duct embolization should be the first intervention attempted in a patient with chylothorax.

The standard approach to ligating the duct remains a low right thoracotomy with ligation of the duct near the aortic hiatus, where it remains as a single trunk. Failure of this approach usually means that the duct was ligated too high in the chest, thus leaving a branch, or branches, patent. The thoracoscopic approach may be useful, although it is not easy, and the incidence of failure may be slightly higher than that achieved with an open procedure. For a left-sided effusion the duct may be approached via a left thoracotomy, as the authors point out. Ligation of the duct for a chylothorax caused by diffuse obstruction of mediastinal lymphatics by tumor, usually lymphoma, tends to have a significantly greater failure rate, and resolution of the effusion is usually accomplished by the treatment of the malignancy. It is in these situations that the pleuropertitoneal shunt may be of more help than simple ligation of the duct. Especially in those patients with higher output, rarely have we been successful simply by trying to effect pleurodesis.

The bottom line to all of this: Act quickly and decisively in managing an iatrogenic chylothorax. We recommend not waiting any longer than 7 days before proceeding with ligation or obliteration of the thoracic duct if the leak has persisted despite total parenteral nutrition.

LRK
ANATOMY AND PHYSIOLOGY OF THE PERICARDIUM

Anatomy

The pericardium consists of two layers. The inner layer, the visceral pericardium, is a single layer of mesothelial cells that is closely adherent to the myocardium. The outer layer, the parietal pericardium, forms a tough fibrous structure and is composed of dense collagen bundles and a small number of elastic fibers. The two layers are separated by a small amount of pericardial fluid.

The parietal pericardium attaches superiorly to the ascending aorta and the superior vena cava. From there, it continues across the superior vena cava, over the right border of the heart and the pulmonary veins, and encircles the inferior vena cava. After the parietal pericardium crosses the inferior vena cava, the inferior pericardium is densely adherent and essentially one with the diaphragm. The parietal pericardium then turns superiorly, just beyond the apex of the heart, and continues over the pulmonary veins, back to the aorta.

There are two sinuses within the pericardial space. They are formed by the pattern of pericardial reflections around the pulmonary vein and the vena cavae posteriorly. The transverse sinus is posterior to the ascending aorta and the pulmonary artery and is anterior to the atria and the superior vena cava. The oblique sinus is located directly behind the left atrium, centered between the pulmonary veins.

Physiology

The normal pericardium contains 15 to 50 ml of serous fluid. The pericardial fluid acts as a lubricant that reduces friction between the pericardial membranes during each heartbeat. Owing to the tough fibrous structure of the parietal pericardium, the pericardial sac is relatively noncompliant. As a result, alterations in the pericardium can have an impact on cardiac hemodynamics.

Pathophysiology

The pericardial sac is noncompliant but can expand if an effusion develops slowly, and it can accommodate large amounts of fluid before hemodynamic consequences occur. If a pericardial effusion develops acutely, however, rapid fluid accumulation overwhelms the ability of the pericardium to distend resulting in increased intrapericardial pressures. This can lead to impaired diastolic filling of the heart, caused by collapse of the right atrium and the right ventricle, and thus limit the stroke volume. As such, patients who develop pericardial effusions with hemodynamic compromise usually develop tachycardia, as it is the sole mechanism through which cardiac output can be increased.

The pericardium can also develop scarring and, consequently, become inelastic, resulting in major hemodynamic effects. A thick, rigid pericardium can prevent the respiratory variation in intrathoracic pressure from being transmitted to the cardiac chambers. Normally, with inspiration, negative intrathoracic pressure is generated; when pericardial constriction is present, this negative pressure is not transmitted to the heart. Consequently, pulmonary venous pressure and left-sided filling are reduced during inspiration. The thicker pericardial sac also results in the pericardial volume becoming static. As such, the reduction in left-ventricular filling during inspiration needs to be compensated for by increased right-ventricular filling, with septal shift toward the left ventricle. The opposite occurs during expiration. This interaction is referred to as ventricular interdependence. Finally, elevated atrial pressures result in rapid diastolic filling, which, because of the inelastic pericardium, abruptly decreases mid-diastole.

PERICARDIAL EFFUSIONS

Etiology

There are several disease processes that can cause pericardial effusions (Table 28.1). Secondary malignancies (usually from the lung or the breast) are the most common causes of pericardial effusions.

PERICARDIAL (CARDIAC) TAMponade

Pericardial (cardiac) tamponade is a medical emergency that occurs when the accumulation of fluid within the pericardial sac results in reduced diastolic filling of the heart and subsequent hemodynamic collapse. The development of tamponade is not related to the amount of fluid that accumulates, but rather to the rate at which the fluid accumulates and the capacity of the pericardium to distend. Therefore, even acute accumulation of small amounts of fluid may be sufficient to cause tamponade.

The first step in managing cardiac tamponade is to make the diagnosis. Patients may present with symptoms of worsening dyspnea, fatigue, or chest pain. Findings on examination can include sinus tachycardia, distended neck veins with elevated jugular venous pressure, and pulsus paradoxus.

When tamponade is suspected on the basis of medical history and physical examination, further evaluation including an electrocardiogram, chest X-ray, and echocardiogram is necessary. The electrocardiogram will usually demonstrate sinus tachycardia and low voltage. An enlarged cardiac silhouette may be evident on chest films. Echocardiography continues to play a major role in the diagnosis of cardiac tamponade. The features to note on echocardiography include the following:

- diastolic collapse of the right heart chambers
- respiratory variation in volumes and flows
- inferior vena cava dilatation

Management of Pericardial Effusions

A wide variety of therapeutic options are available to manage pericardial effusions. These options include simple observation,

use of anti-inflammatory or antineoplastic chemotherapy, pericardiocentesis, percutaneous balloon pericardiotomy, and surgery. Because of the lack of prospective studies evaluating the efficacy of the different treatments, the optimal management of this condition remains a matter of controversy.

When determining the choice of treatment for pericardial effusions, a number of factors need to be considered. These factors include the presence or absence of tamponade, the underlying diagnosis or etiology of the effusion, the potential for recurrence, and the resources available at one’s institution.

**Pericardiocentesis**

Pericardiocentesis can be performed at the bedside or under echocardiographic or fluoroscopic guidance. Local anesthesia is usually adequate. To begin, the area between the xiphoid process and the costal margin is infiltrated. An 18-gauge spinal needle attached to a three-way stopcock and syringe is inserted between the two structures and advanced toward the left shoulder at a 45-degree angle. The needle should be gently aspirated as it is being advanced. If the procedure is being performed without imaging, attaching the needle to a precordial electrocardiographic lead can help to identify when the myocardium is breached, as ST elevation, which resolves when the needle is withdrawn, will be noted. Once the pericardial space is entered, a guide wire is advanced, and a pigtail catheter is introduced by use of a modified Seldinger technique. Fluid that is removed can be sent off for further evaluation (biochemical, microbiologic, and cytologic examination).

Major complications of pericardiocentesis include laceration and perforation of the myocardium and the coronary vessels. Other complications that have been reported include air embolism, pneumothorax, arrhythmias, and puncture of the peritoneal cavity or abdominal viscera. The incidence of major complications ranges from 1.3% to 1.6%, and safety has improved with the use of echocardiographic or fluoroscopic guidance.

One advantage of pericardiocentesis is the avoidance of general anesthesia. It can also provide effective immediate improvement in unstable patients with cardiac tamponade. However, not all pericardial effusions are appropriate for pericardiocentesis—namely, small, posterior, and loculated effusions. Other disadvantages include high recurrence rates and reduced diagnostic yield. A retrospective study comparing outcomes after pericardiocentesis and surgery found a recurrence rate of 16.5% in patients who underwent pericardiocentesis, compared with 4.6% in patients who underwent surgery. The diagnosis of malignancy was confirmed in 59% of patients who underwent percutaneous procedures, compared with 62% of patients who underwent open drainage.

**Percutaneous Balloon Pericardiotomy**

Percutaneous balloon pericardiotomy is performed in the cardiac catheterization laboratory using local anesthesia and intravenous sedation, with fluoroscopic and echocardiographic guidance. The pericardium is entered with an 18-gauge pericardial needle by use of a standard subxiphoid approach. A guide wire is then advanced into the pericardial space, a catheter is introduced, and pericardial fluid is drained for laboratory studies. Radiographic contrast medium is then injected into the pericardial space to aid visualization. The catheter is removed, and the tract is dilated using a 10F–14F dilator. A low-profile balloon-dilating catheter containing some radiographic contrast medium is inserted over the guide wire and positioned across the parietal pericardium. To ensure adequate opening of the parietal pericardium, a series of balloon inflations are performed. A pigtail catheter is often left in the pericardial space for 24 hours and removed once complete resolution of the effusion has been confirmed by echocardiography. Chest X-rays are also performed after the procedure to exclude the possibility of a pneumothorax.

There have been several small studies describing the use of this modality as an alternative to a surgically created pericardial window. The largest trial, which was part of a multicenter registry, involved 50 patients. In that trial, the modality was considered successful for 46 patients, after a mean follow-up of 3.6 months. The procedure was deemed unsuccessful for four patients, either because of recurrence of effusion or tamponade, bleeding requiring surgical intervention, or persistent catheter drainage requiring surgery.

**Subxiphoid Pericardial Window**

Subxiphoid pericardial window is a surgical procedure that can be performed with the patient under either local or general anesthesia. Because of the lack of evidence in the literature, the optimal anesthetic management for patients with pericardial tamponade who require a subxiphoid pericardial window remains open to debate. The advantages of using general anesthesia include improved surgical evacuation of pericardial contents and improved patient comfort. In cases where general anesthesia is administered to patients with significant hemodynamic compromise, the patient should be prepped and draped, with the surgeon ready to begin, before induction of general anesthesia. Unpublished data have also suggested that there is no difference in outcomes between patients managed with local anesthesia and sedation and those managed with general anesthesia (Fig. 28.1).

For the subxiphoid approach, a vertical incision is made that begins at the xiphoid–sternal junction and extends inferiorly by 4 to 5 cm. The linea alba is identified and divided with care so that the peritoneum is not breached. To provide better exposure the xiphoid process is resected. The costal margin is elevated, allowing the diaphragm and peritoneal fat to be separated by use of a sponge stick, until the pericardium is identified. The pericardium is opened using shallow strokes of a blade to minimize risk of injury to the underlying myocardium. Entry into the pericardial space is confirmed when an initial gush of fluid occurs. When the
Chapter 28: Pericardial Procedures

Fig. 28.1. Subxiphoid pericardial window. (A) An upper midline incision centered over the xiphoid process is performed, with sharp dissection down through the linea alba. The xiphoid can be resected for better exposure. (B) The sternum and costal margin are elevated with a retractor. A combination of blunt dissection with a sponge stick and sharp dissection with electrocautery is then used to dissect the soft tissue superiorly, ultimately exposing the inferior pericardium. Once exposed, the pericardium is incised with scissors or a knife, the pericardial sac is digitally explored, and a large portion of the inferior pericardial sac is excised. A right-angle chest tube is then placed into the sac, from a separate incision.

effusion is hemorrhagic, it can be difficult to determine whether cardiac injury has occurred. The surgeon should therefore be vigilant to monitor the patient’s hemodynamic status at this time.

Once the effusion is drained and samples are sent for culture and cytologic examination, a finger is used to explore the pericardial space and to break up any loculations. A piece of pericardium is then resected (as large as is possible to safely remove) and sent for microbiologic assessment and histologic examination. One or two 28F right-angle chest tubes are placed through stab incisions on either side and inferior to the incision and positioned in the inferior aspect of the pericardial space. The linea alba is closed using interrupted nonabsorbable sutures, and the skin and the subcutaneous tissue are closed using absorbable sutures, in the standard fashion. The chest tubes are left in place until the drainage is less than 100 ml/day and when complete drainage of the pericardium has been confirmed by echocardiography.

In published case studies, the recurrence rates for patients who underwent open subxiphoid drainage range from 0% to 9.1%. The majority of these studies reported only a single method of drainage. One retrospective study found that the recurrence rate for patients who underwent pericardiocentesis. Similarly, another retrospective study found that the recurrence rate after open subxiphoid drainage was lower (4.6%) than that after percutaneous catheter drainage (16.5%).

Video-Assisted Thoracoscopic Approach

Thoracotomy Approach

Open thoracotomy can be a useful approach for hemodynamically stable patients who present with a pericardial effusion. It can also be useful for those patients who require concurrent performance of additional procedures, such as lung biopsy. A left-sided approach is generally preferred, as a larger amount of pericardium is accessible on the left side. Patients are placed supine, with the left side elevated by approximately 30 degrees. Single-lung isolation is preferred to allow adequate visualization.

The incision is made in the inframammary crease and the fourth or fifth intercostal space is entered. The pericardium can be visualized once the lung is retracted laterally. The pericardium is opened with care taken not to injure the phrenic nerve or the underlying myocardium. When this approach is used a large piece of pericardium can be resected, to minimize the incidence of recurrence. A large, 28F chest drain is usually placed in the left pleural cavity and the thoracotomy wound is closed in the standard fashion.

The video-assisted thoracoscopic surgery (VATS) approach is a safe and effective approach that is minimally invasive and allows concomitant exploration of the pleural cavity. Effective single-lung isolation is mandatory, and, therefore, this approach is not suitable for patients who are hemodynamically unstable. Although the approach can be performed on either side because of the proximity of the pericardium to the chest wall, a left-sided VATS approach is technically more challenging (Fig. 28.2).

After induction of general anesthesia the patient is placed in the lateral decubitus position. The incision for the camera port is usually made in the seventh or eighth intercostal space (depending on the patient’s body habitus), in the posterior axillary line. A utility incision is then made anteriorly, under direct vision, in the fifth anterior intercostal space. To allow for the use of several different instruments through the same incision, the incision is made approximately 4 to 5 cm in length.
Fig. 28.2. Transthoracic pericardial window. (A) The patient is placed in a full right-lateral decubitus position, and three ports are placed into the left hemithorax (one in the eighth intercostal space posterior axillary line and two at approximately the midscapular line, in the sixth and ninth intercostal spaces). (B) Portions of the pericardium are resected, ensuring that the phrenic nerve is visualized and spared. At the end of the procedure, a chest tube is placed into the hemithorax via the posterior axillary incision.

Next, the phrenic nerve is identified, and an incision is made anterior to it. A generous pericardial window is created by resecting a piece of anterior pericardium. This is repeated posterior to the phrenic nerve as well. If the procedure is being performed on the right side, a single large pericardial window is created, since the phrenic nerve runs closer to the hilum.

Several studies have reported recurrence rates ranging from 0% to 8% after creation of a thoracosopic pericardial window. A retrospective study that investigated outcomes after subxiphoid window and VATS pericardial window noted recurrence rates of 8% and 10%, respectively. That study also noted that time of anesthesia for thoracoscopy was significantly longer (117.1 vs. 81.1 minutes).

**Pericardial Sclerosis**

Intrapericardial sclerosis induces an inflammatory response that will obliterate the pericardial space. The pericardial space is accessed via percutaneous catheter drainage or after surgical drainage (subxiphoid window, thoracotomy, or VATS). The procedure is performed once drainage through the catheter has been less than 100 ml for more than 24 hours. Local anesthetic, such as lidocaine, is instilled through the catheter, followed by instillation of the sclerosing agent. The drain is kept clamped for 3 hours and then removed.

Sclerosing agents that have been used include tetracycline, doxycycline, bleomycin, and thiotepa. These various sclerosing agents appear to have equal effectiveness in minimizing recurrence rates after drainage of pericardial effusions. However, it appears that some agents may be associated with more complications. Doxycycline can result in intense pain with most patients who experience pain requiring intravenous analgesia. More than half of the patients who receive doxycycline also develop fevers higher than 38.5°C. Alternatively, thiotepa does not result in pain and very rarely generates a pronounced febrile response. In addition, it has been shown to be more cost-effective.

**CONSTRUCTIVE PERICARDITIS**

Constrictive pericarditis can occur after any disease process that affects the pericardium (Table 28.2).

Signs and symptoms of constrictive pericarditis are analogous to those seen with fluid overload (elevated jugular venous pressures, ascites, and peripheral edema) and/or to diminished cardiac output in response to exertion (fatigue and dyspnea on exertion). Echocardiographic examination is essential for patients being evaluated for constrictive pericarditis. Findings include a septal bounce that is related to respiratory variations in the motion of the ventricular septum, and decreased transmural flow velocity.

Computed tomography may demonstrate increased pericardial thickness and calcification, but it is important to note that a normal appearance on computed tomography does not exclude the diagnosis of constrictive pericarditis. Gated cardiac magnetic resonance imaging allows direct visualization of the pericardium that normally has a low magnetic resonance imaging signal intensity. Features that are characteristic of constrictive pericarditis on cardiac magnetic resonance imaging include increased pericardial thickening and dilatation of the inferior vena cava.

Cardiac catheterization occasionally may be required to confirm the diagnosis of constrictive pericarditis for patients with nondiagnostic echocardiographic findings. The major hemodynamic findings include elevated right-atrial pressure, rapid x and y descents in the atrial pressure curves, and “square-root” signs in the right-ventricle and left-ventricle pressure tracings.

Computed tomography may demonstrate increased pericardial thickness and calcification, but it is important to note that a normal appearance on computed tomography does not exclude the diagnosis of constrictive pericarditis. Gated cardiac magnetic resonance imaging allows direct visualization of the pericardium that normally has a low magnetic resonance imaging signal intensity. Features that are characteristic of constrictive pericarditis on cardiac magnetic resonance imaging include increased pericardial thickening and dilatation of the inferior vena cava.

Cardiac catheterization occasionally may be required to confirm the diagnosis of constrictive pericarditis for patients with nondiagnostic echocardiographic findings. The major hemodynamic findings include elevated right-atrial pressure, rapid x and y descents in the atrial pressure curves, and “square-root” signs in the right-ventricle and left-ventricle pressure tracings.
(a dip-and-plateau pattern in the ventricular pressure curves caused by rapid early filling and limited late filling).

The most effective approach to manage constrictive pericarditis remains unclear as no prospective studies have compared outcomes in patients undergoing medical therapy with those undergoing operation. While the natural history of constrictive pericarditis remains unknown observational studies and case reports suggest that patients who do not undergo surgical intervention experience progression of symptoms and early death. Conversely, it has been reported that a large number of patients who underwent pericardiectomy experienced improvement in their symptoms, as well as improvement in their quality of life. Therefore, pericardiectomy remains the treatment of choice for patients with symptomatic constrictive pericarditis.

**Pericardiectomy**

Pericardiectomy is the accepted approach to manage patients with symptomatic constrictive pericarditis. However, opinions differ with regard to the ideal surgical approach, the extent of the pericardiectomy, and the need for cardiopulmonary bypass.

The two standard surgical approaches that have been used are (1) left anterolateral thoracotomy and (2) median sternotomy. There are few reports that address the issue of surgical approach, and the choice of approach appears to be left to the surgeon's personal preference. Left anterolateral thoracotomy provides excellent exposure of the left ventricle and, consequently, permits a more complete release of the left ventricle. Median sternotomy allows for a more extensive pericardiectomy to be performed with better exposure of the right ventricle and great veins. A retrospective study that compared the two surgical approaches in a cohort of 36 patients demonstrated that outcomes and mortality rates were similar for both approaches. Regardless of the approach used, all patients require invasive hemodynamic monitoring with an arterial and central venous catheter. In patients with significant hemodynamic compromise, a pulmonary artery catheter may also be required.

The extent of pericardiectomy to be performed is also controversial. A total pericardiectomy is defined as a wide excision of the pericardium, with the phrenic nerves defining the posterior extent, the great vessels (including the intrapericardial portion and the superior vena cava–right atrium junction) defining the superior extent, and the diaphragmatic surface (including the inferior vena cava–right atrium junction) defining the inferior extent of the pericardial resection. A partial pericardiectomy is defined as any excision that is less than a total pericardiectomy. A retrospective study that compared 338 patients who underwent total pericardiectomy with 57 patients who underwent partial pericardiectomy demonstrated that the risk of death was 4.5 times higher for patients who underwent partial pericardiectomy. This study also demonstrated better long-term survival and improved functional status (New York Heart Association functional classification) for patients who underwent total pericardiectomy.

The use of cardiopulmonary bypass as an adjunct to pericardiectomy remains a matter of debate. Some believe that the use of cardiopulmonary bypass facilitates surgical dissection by emptying the ventricular cavities (to define the appropriate plane of dissection), as well as by providing better access to the diaphragmatic surface of the left ventricle (thus allowing for a more extensive pericardiectomy). Cardiopulmonary bypass is also helpful in situations where inadvertent myocardial injury has occurred during dissection. The major disadvantage of cardiopulmonary bypass is the potential for increased bleeding with the systemic heparinization.

**Median Sternotomy**

The patient is placed in the supine position, with the arms tucked to the side, and a median sternotomy is performed in the usual manner. Once the sternum is divided, adhesions, if any, are dissected away, both pleural spaces are opened, and the right and left phrenic nerves are identified. The aim of this procedure is to entirely resect the pericardium between the phrenic nerves and to mobilize the remainder of the cardiac surfaces within the pericardium (Fig. 28.3).

There are often limited loculated pericardial spaces, particularly around the great vessels and the diaphragm. To attempt to identify the pericardial space, transverse incisions are created in these areas. While creating the initial flap, the surgeon must exercise caution to avoid causing injury to the coronary artery. The pericardium can be densely adherent in the region of the coronary arteries, and in this instance it may be safer to leave small islands of pericardium on the heart. Bone-cutting instruments may be necessary when areas of calcification are encountered. Calcified deposits that extend into the myocardium should be left in place and not removed.

The pericardium over the left ventricle should be freed first. If the pericardium over the right ventricle is freed first, increased preload (improved diastolic filling of the heart) and afterload (left ventricle still restricted by thick pericardium) can result. This can cause acute right-ventricular dilatation and failure, with devastating consequences. The pericardium is resected between the phrenic nerves, and the heart is dissected free from the thick, constrictive pericardium, all the way down to both atria. Once the pericardiectomy is complete, mediastinal and pleural drains are placed, and the sternum is closed in the usual manner.

**Left Anterolateral Thoracotomy**

The patient is positioned supine, with the left side elevated by 45 degrees and the left hand placed behind the buttocks. An inframammary incision that curves posteriorly to overlie the fifth rib is made. The chest is entered through the fifth interspace. Removing the fifth costal cartilage may provide better exposure. The left internal mammary vessels must often be divided, and the left phrenic nerve is carefully identified (Fig. 28.4).

Once again, the loculated spaces that are present near the diaphragm and great vessels are a convenient starting point for the pericardiectomy. The pericardium is dissected free, and a tongue of pericardium is left attached to the phrenic nerve along its length. The pericardial resection is then extended posterior to the phrenic nerve, onto the left atrium, and then is resumed anterior to the phrenic nerve, ideally continuing as far as the right atrioventricular groove. The necessary precautions to avoid causing injury to the coronary vessels and myocardium should be taken.

**SUGGESTED READINGS**

Section I: General Thoracic Surgery

Fig. 28.3. Sternotomy and pericardiectomy. (A) A full sternotomy incision is performed, both pleural spaces are entered, and both phrenic nerves are identified. The pericardium is incised and freed first over the left ventricle. (B) A complete pericardiectomy includes removal of the pericardium extending laterally to both phrenic nerves and inferiorly from the diaphragm, extending superiorly to the aorta, pulmonary artery, and right atrium. Three chest tubes are placed before closure of the sternum (two pleural and one beneath the sternum).

Fig. 28.4. Left anterolateral thoracotomy and pericardiectomy. (A) The patient is positioned supine, with the left side elevated by 45 degrees and the left hand placed behind the buttocks. An inframammary incision that curves posteriorly to overlie the fifth rib is made. The chest is entered through the fifth intercostal space. (B) The pericardium is dissected free, and a tongue of pericardium is left attached to the phrenic nerve along its length. The pericardial resection is then extended posterior to the phrenic nerve, onto the left atrium, and then is resumed anterior to the phrenic nerve, ideally continuing as far as the right atrioventricular groove.

**EDITOR’S COMMENTS**

The management of a pericardial effusion depends to a great extent on the suspected etiology of the effusion and whether or not tamponade physiology is present. Simple pericardiocentesis may be the only procedure necessary if there is no evidence of tamponade and fluid for diagnosis is required. Previously, pericardiocentesis was carried out with the needle attached to an ECG to determine whether the needle was within the myocardium. The use of echocardiography to visually determine needle placement clearly is the more definitive procedure.

Despite the feasibility of catheter drainage of the pericardium as well as the development of balloon pericardiostomy, the definitive procedure for the treatment of a symptomatic malignant pericardial effusion remains the subxiphoid window. As the authors note, the procedure may be carried out with either local or general anesthesia but our preference has been to use general anesthesia. The surgeon must be present at the time of induction of anesthesia and the patient should be prepped and draped so that rapid access to the pericardium may be gained should there be a significant drop in blood pressure. Exposure to the pericardium is significantly enhanced by resecting the xiphoid process and applying downward pressure on the diaphragm. It is well known that the window itself is likely obliterated fairly rapidly and the therapeutic value of the pericardial window is the facilitation of visceral to parietal pericardial symphysis. It is this obliteration of the pericardial space that is likely the cause of the low recurrence rate following the performance of a subxiphoid pericardial window. The subxiphoid approach is far preferable to the left anterior thoracotomy approach, in my opinion. A right-angled chest tube should always be left in the pericardial sac following the subxiphoid window procedure with the tube placed to suction drainage. The operative procedure is further aided by the use of transesophageal echocardiography to define the location of the effusion and specifically whether there are loculations that need to be broken up and whether there is significant fluid in the posterior pericardium. A generous swath of anterior pericardium should be taken and submitted for pathologic examination.

The treatment of constrictive pericarditis is made all the more difficult because the distinction between a restrictive cardiomyopathy, which would not benefit from pericardiectomy, and constriction must be made. This distinction may rely on the imaging demonstration of thickened pericardium in addition to the echocardiographic or cardiac catheterization data. Depending on the extent of the constriction the procedure may be more safely carried out with the use of cardio-pulmonary bypass, but this decision must be made on a case-by-case basis. It is also critically important, as the authors point out, to relieve the constriction of the left ventricle prior to releasing the right ventricle to avoid right ventricular dilatation. A total pericardiectomy is the optimal procedure.

LRK
INTRODUCTION
Albeit the most common primary tumor of the pleura, malignant pleural mesothelioma is a very rare cancer, only several percent as common as nonsmall cell lung cancer in the United States. The tumor is most commonly linked to asbestos exposure and typically occurs several decades after exposure. Despite the relatively recent mandates to protect the public from asbestos, it is expected that the incidence of mesothelioma will continue to increase for the foreseeable future.

The natural history of mesothelioma, which is almost always unilateral, is inexorable local progression with encasement of the lung and invasion of the chest wall, diaphragm, and/or mediastinum. The majority of patients will succumb to the disease less than a year from the time of diagnosis. Although the disease has a reputation for being a purely localized tumor, at least half the patients will have occult metastases at the time of their demise. The clinical manifestations of metastases have become more commonly noted in some patients who have undergone aggressive multimodal approaches and are fortunate enough to have an extended survival.

Patients will commonly present with dyspnea secondary to a pleural effusion. Other presenting symptoms, such as weight loss or pain from chest wall invasion, are even more ominous and tend to reflect more advanced or aggressive form of the cancer. Radiographic studies may reveal only the pleural effusion and no other detectable disease. Patients with a pleural rind will commonly demonstrate a contracture of the hemithorax as a result of decrease in the size of the rib interspaces, which can be easily seen on a plain chest film.

Unless a history of asbestos exposure is offered, mesothelioma may not be immediately considered and the diagnosis will be delayed. Further delaying the diagnosis is the common event of a negative cytology on fluid withdrawn by thoracentesis. Ultimately the recurrence of the effusion or the recalcitrance of the clinical complaints to attempted interventions will, hopefully, lead the patient to a physician experienced with mesothelioma. Ideally this will be a thoracic surgeon facile in dealing with pleural diseases.

Establishing a diagnosis and simultaneously palliating the symptoms caused by the effusion can be accomplished thorascopically through a single 1-cm incision. If the patient is potentially a candidate for an aggressive treatment protocol, then the ideal situation is for the surgeon who would be performing the therapeutic operation to perform the diagnostic/palliative procedure. The reasons for this are twofold. The first is that mesothelioma has a propensity to seed incisions. Hence, it is often desirable to excise the biopsy incisions at the time of the thoracotomy. Consequently, if the same surgeon performs both procedures, the incisions used for the biopsy procedure can be placed in line with a potential thoracotomy, such that they could be excised as part of the thoracotomy without compromise of chest wall integrity or the need for an additional incision. In addition, the surgeon who performs both procedures can decide between pleurodesis or placement of a long-term indwelling catheter as the best route of palliation that will not interfere with future operations or therapeutic interventions.

Pemetrexed-based chemotherapy is, ostensibly, the standard of care treatment for pleural mesothelioma. Beyond this chemotherapy, essentially all treatments—including surgery—remain investigational. Nonsurgical modalities that have been used to treat this malignancy include many combinations of systemic therapy, radiation therapy, and many types of immunotherapies.

To date, however, the treatments that have met with the greatest measure of success in extending life are surgery-based multimodal treatments. Again, hobbled by the scarcity of this cancer and the small number of patients undergoing operation for this cancer, large randomized prospective trials do not exist to validate the role of surgery in treating this cancer. It is, therefore, appropriate that any patient being offered surgery for this cancer should be the focus of a multidisciplinary panel discussion to assess the options. Patients undergoing operation for mesothelioma should, in addition to standard disclosures for informed consent, be aware that surgery is not the standard of care. Furthermore, as mesothelioma remains an incurable cancer, patients should understand that although the procedure is done with “curative intent,” the realistic goal is extension of life beyond what would be anticipated with less aggressive approaches. Ideally, patients undergoing surgery for this cancer should be part of a clinical trial that will accrue data to further the field and help establish optimal treatments for future patients.

Patient selection for surgery-based treatments can vary from institution to institution, but the general principles observed by all groups are that the cancer must appear confined to one hemithorax and the patient must be at reasonable risk for the proposed procedure. Areas of controversy are typically stage-related inclusion/exclusion criteria, particularly N2 lymph nodes, and mesothelioma subtype. As a general rule, patients with nonepithelial histologies are much less likely to enjoy any significant period of remission compared to patients with epithelial subtypes. Some surgeons will have an age limit, whereas others do not. As pemetrexed-based chemotherapy is standard, essentially all surgery-based treatments will incorporate this, but whether it is given as a postoperative adjuvant, preoperative neoadjuvant, or both is also currently institution dependent. Finally use of other modalities, if any, combined with surgery, remains institution dependent.
Because microscopic disease remains after any operation for a pleural malignancy, the goal of surgery in these multimodal protocols is to achieve a macroscopic complete resection. There are two approaches toward achieving this goal, operations that take the lung or operations that spare the lung.

The lung-sacrificing approach, extrapleural pneumonectomy, currently is the most common approach. This operation involves resection of the parietal pleural envelope en bloc with the lung, diaphragm, and pericardium. The pericardium and diaphragm are then reconstructed with prosthetic patches. This procedure has the advantages of standardized techniques/nomenclature, leaving the least amount of residual microscopic disease and, because the lung is absent, the ability to deliver full-dose adjuvant hemithoracic radiation. The obvious disadvantages are the risk and lifestyle consequences of pneumonectomy and the smaller pool of patients, many of whom are elderly, who are appropriate candidates for pneumonectomy.

Whereas extrapleural pneumonectomy enjoys uniformity in technique and nomenclature, lung-sparing surgery enjoys neither. Some surgeons intentionally leave behind gross disease, while others use it to achieve a macroscopic complete resection. Terms to describe this procedure include palliative pleurectomy, palliative debulking, pleurectomy, decortication, pleurectomy-decortication, and radical pleurectomy. Radical pleurectomy is the term used by the author and is defined as a procedure used to achieve a macroscopic complete resection that spares the lung and, whenever possible, the phrenic nerve, and as much of the diaphragm and pericardium as possible. The advantages of radical pleurectomy are the obvious benefits of lung preservation which, compared to pneumonectomy, has the potential to translate into less operative risk resulting in more patients being eligible for surgery-based treatment, better postoperative quality of life with greater reserve, and, consequently, more treatment options when the inevitable recurrence occurs. The disadvantages include lack of standardization, unique technical challenges, the need for judgment as to when the resection is complete, inability to incorporate standard adjuvant hemithoracic radiation, and, almost certainly, more residual microscopic disease than after an extrapleural pneumonectomy.

The modalities that have been used as intraoperative adjuvant therapies are hyperthermic chemotherapy lavage and photodynamic therapy. Again, with the exception of pemetrexed-based chemotherapy none of these, in any combination, is considered the standard of care.

Once a patient has been reviewed in a multidisciplinary conference and has elected to pursue a surgery-based treatment while understanding and recognizing other options, we initiate an evaluation to determine if the patient is a safe and appropriate candidate from an oncologic perspective. Our preoperative safety workup includes all of the usual studies and evaluations for a major pulmonary procedure, but with special emphasis on pulmonary function, cardiac function, and nutritional status. With respect to staging, our standard noninvasive preoperative workup includes a chest computed tomographic (CT) scan, brain imaging, and a positron emission tomography (PET) scan. MRI is utilized selectively when there is a question as to the extent of diaphragmatic or mediastinal invasion. We routinely perform a bronchoscopy and outpatient laparoscopy with peritoneal lavage to rule out radiographically occult disease. If the contralateral thorax has any questionable findings, we incorporate a VATS inspection of that hemithorax at the same time. Mediastinoscopy or endobronchial ultrasound (EBUS)-guided biopsies of the mediastinal lymph nodes also is commonly performed. Until our most recent study the status of the mediastinal (N2) lymph nodes had not demonstrated significant correlation with outcome. Now that we have established that mediastinal nodal involvement is correlated with outcome, although not an exclusion criterion like contralateral chest or abdominal disease, we also incorporate mediastinal staging with EBUS as part of our invasive staging workup.

**OPERATIVE TECHNIQUES**

**Diagnosis, Palliation of Pleural Effusion, and Invasive Staging**

Occasionally, a diagnosis can be established on the basis of fluid cytology from a thoracentesis or a closed pleural biopsy. More commonly, however, a surgical biopsy is required. This is best accomplished using a thoracoscopic technique and can be performed through a single 1-cm incision. After medical clearance the patient is brought to the operating room and once general anesthesia is induced, a bronchoscopy is performed. We have, on one occasion, discovered contralateral endobronchial metastases that served as a contraindication for any aggressive treatment options. The expected appearance of the airway, in the setting of a large effusion or bulky pleural disease, is extrinsic compression. If there is a significant amount of sequestration in the airway, the surgeon should plan on performing a completion toilet bronchoscopy at the conclusion of the operation in order to maximize postoperative lung expansion.

**Diagnosis and Palliation for Patients Presenting with Effusion**

Once the patient is turned to the lateral decubitus position, the position of the double-lumen tube or bronchial blocker is confirmed and the lung on the operative side is isolated. After preparing the skin and positioning the patient, a potential thoracotomy incision is drawn on the chest wall. It is our practice to enter the chest through a serratus-sparing thoracotomy through the sixth interspace or the bed of the resected seventh rib. Starting in the anterior axillary line and working forward as necessary, the chest is sounded with a 22-gauge needle, along the potential future incision line, until fluid is encountered. This sample is saved for microbiology stains and cultures if there is any chance that the effusion is secondary to an infectious process. Having identified a safe site for entry, a local cutaneous and intercostal block is performed with a long-acting local anesthetic and a 10-mm incision is then created. The chest is then entered through this incision and fluid is aspirated to allow visualization. The fluid is collected for cytologic evaluation in the event that lesional tissue is not confirmed on the pleural biopsies. It is our practice to send an entire suction canister of pleural effusion for this purpose.

A 5 mm 30 degree thoracoscope is then introduced and the hemithorax is inspected. A small suction or blunt laparoscopic instrument can then be placed in through the same incision, alongside the thoracoscope, and loculations are disrupted and any remaining fluid is aspirated. Mediastinoscopy, or any other narrow, biopsy forceps are then introduced. The 30 degree angle allows the surgeon to maneuver the scope and the biopsy forceps without interference. In early-stage mesothelioma visual inspection within the chest may reveal only an injected-appearing pleura, in which case extensive parietal pleural biopsies are performed. More advanced stages will reveal popular or nodular lesions that will eventually coalesce into plaques coating the chest wall, lung, diaphragm, and mediastinum. It is critically important to never violate the visceral pleura or a persistent...
air leak can result. All biopsies should be taken from the parietal pleura. Biopsy specimens need to be sent to the pathologist for frozen section analysis and “lesional tissue” needs to be confirmed along with a sufficient quantity of specimen for the pathologist to run all additional tests required to render a final diagnosis. Although most diagnoses are currently made on the basis of morphology and the immunohistochemical profile, some institutions may still elect to perform electron microscopy that may require special handling of the specimen and this should be discussed with the pathologist. This is occasionally required when patients are having repeat biopsies for previous nondiagnostic surgical biopsies. Molecular or genetic analysis of biopsy specimens may also be undertaken in order to definitively establish a diagnosis.

At the conclusion of the specimen sampling, palliation of the effusion should be considered. If, based on the proposed treatment plan, the patient is going to have another procedure in the near future, or if the lung fails to fully expand, then a cuffed, silicone pleural catheter with a valve should be placed with the intent for this to remain in place on a chronic basis to deal with recurrent effusion. If the treatment plan does not anticipate further surgery, or the operative surgeon desires obliteration of the pleural space, then a chemical pleurodesis should be performed. One critical error is to instill talc into a chest cavity where visceral pleural–parietal–pleural apposition does not occur. In this setting, with entrapped lung, a residual pleural space will remain. If it gets infected, it can be very difficult to treat and if talc, a permanent foreign body, is in the chest cavity, this can spiral into an incurable empyema that will be the direct cause of the patient’s death. If the patient will be a candidate for a surgery-based treatment, then the tube should be brought out in the same incision line, close enough to the VATS port that it can be incorporated in an excision at the time of thoracotomy. If the patient is not going to be a candidate or wishes not to have further surgery, then the tube should be brought out along the anterior axillary line at the level of the costophrenic recess. This will allow for better drainage. In either case, the tube should be directed posteriorly, to drain fluid at the diaphragm, and then extend to the end of this length paraspinally in a cephalad direction. The single VATS incision is then closed with absorbable sutures in a watertight manner. Depending upon the patient, this procedure may be performed on an outpatient basis. Commonly, however, these patients are best served by staying in the hospital overnight such that they can receive training on how to drain their tube in addition to determining an effective pain-control regimen. Finally, it is often valuable to obtain a CT scan following drainage of the fluid with the tube on suction. This will give the best indication of whether or not the disease appears to be a true pleural cancer or if there are pulmonary nodules more suggestive of metastatic disease. Often these nodules will not be visible on the preoperative CT scan because of the presence of fluid and lung compression.

**Diagnosis for Patients Presenting with a Pleural Rind**

If a patient has a thick pleural rind, then the diagnosis can be obtained without entering the pleural space. Based on the CT scan, a spot along a potential future thoracotomy incision is selected where there appears to be significant pleural tumor thickness. Under general anesthesia, the area is infiltrated with local anesthetic. Depending upon the thickness of the soft tissue between the skin and the target, incision can be as small as 1 cm or may need to extend to 3 to 4 cm. The soft tissue is incised and the dissection is carried into the underlying interspace where a hard, white mass will be encountered. Using a scalpel, or a biopsy forceps, specimens are harvested. Great care needs to be taken to avoid full-thickness penetration of the tumor and violation of the underlying visceral pleura. Again, it is imperative to confirm the presence of lesional tissue. It would be the exception to have a free pleural space, in the presence of bulky pleural disease and the absence of an effusion, so there is unlikely to be a role for video thorascopy in these cases. If additional tissue is required, it is best to harvest tumor along the interspace rather than risk deeper biopsies that may enter the lung. Once the pathologist has confirmed the presence of lesional tissue and a sufficient quantity of specimen to establish a diagnosis has been obtained, the incision is closed after irrigating with sterile water or saline. With the incision filled with liquid, the area is observed during several breaths to assure that the fluid does not drain into the chest. This would indicate the presence of pleural patency and may require placement of a chest tube. The anesthesia team is then requested to deliver a prolonged Valsalva maneuver and the site is inspected for bubbles. If it appears that the lung has been entered, a soft drainage tube should be placed in the bed of the incision and treated like a chest tube. If there are no bubbles and the fluid level is static, then the incision can be closed in layers without any drainage.

**INVASIVE STAGING STUDIES**

Given the fact that surgery for mesothelioma is investigational and, in reality, palliative, we feel strongly that every effort should be made to rule out any extrathoracic disease. Beyond radiographic studies, we routinely perform invasive staging that includes bronchoscopy, EBUS, and laparoscopy. As indicated by the preoperative imaging, we selectively perform contralateral VATS and, on occasion, upper endoscopy. In our protocols mediastinal nodal involvement is not an exclusion criterion, but any extrathoracic disease does exclude the patient from a surgical approach. Laparoscopy is used to rule out diaphragmatic transgression and/or peritoneal metastases. We have, on several occasions, uncovered occult peritoneal metastases that were documented with cytologic analysis of a saline peritoneal lavage. In addition, we have discovered both false positive and false negative readings on the radiographic interpretation of diaphragmatic invasion. If a patient is suspected of having a fused abdomen, then we will forego the laparoscopy instead obtaining a dedicated abdominal/pelvic CT to complement the PET scan. If these reveal any concerning findings and the patient is committed to pursuing surgery, then we will go as far as performing a laparotomy to rule out abdominal disease prior to proceeding with a radical pleurectomy.

Assuming nothing is discovered on bronchoscopy (or contralateral VATS) the patient is placed in the supine position for the laparoscopy. The abdomen is entered through a 5-mm infraumbilical port. A 30-degree laparoscope is used. After confirming that there was no injury upon entry, a second 5 mm subcostal port is placed on the side of the tumor. At this point the entire peritoneal cavity is explored. The subcostal port is used to provide sufficient visualization of the undersurface of the diaphragm. Any suspicious areas are sampled for histologic analysis. Otherwise, random peritoneal biopsies are then performed. Following this 1 L of sterile saline is instilled, the abdomen is agitated, and the fluid is collected for cytologic analysis.

**RADICAL PLEURECTOMY AND EXTRAPLEURAL PNEUMONECTOMY TECHNIQUES—AS PART OF A MULTIMODAL APPROACH**

**Introduction**

There is currently no incontrovertible data to support surgery for mesothelioma, let alone a specific approach. What does...
appear clear is that a macroscopic complete resection is the goal, with residual gross disease after resection almost always translating into a poor oncologic outcome. As a result, if the surgeon elects to proceed with a lung-sparing procedure, it should be a radical pleurectomy with the goal of a macroscopic complete resection. It is commonly held that sparing the lung is an intraoperative decision, based principally upon the extent of disease within the fissure. The author has published evidence dispelling this notion and demonstrating that it is possible to achieve a macroscopic complete resection with lung-sparing surgery in essentially any patient, even those with very bulky disease, extension into the chest wall, and/or extensive involvement of the fissure. The exception is the patient with invasion of the major bronchovascular structures but, in over 100 consecutive cases, with many patients having tumor volumes in excess of 1,000 mL, this has not been encountered. Such a patient, assuming the cancer had selectively invaded the lung but not transgressed the diaphragm and/or mediastinum, would require an extrapleural pneumonectomy.

Whether or not lung-sparing surgery proves equal, inferior, or superior to extrapleural pneumonectomy remains to be established. What is clear, however, is that sparing the lung results in a slight broadening of the candidate pool for surgery-based therapies and, almost certainly, results in a superior quality of life to what would be expected with an extrapleural pneumonectomy.

Positioning and Incision

In addition to the standard preparation for a procedure of this magnitude, it is critical to confirm that any special equipment and/or personnel are available. Examples of such items would be an argon beam coagulator for chest wall cautery and photodynamic therapy or heated chemotherapy, requires the requisite additional layers of preparation.

Prior to positioning the patient, a nasogastric tube should be placed as this will facilitate in identification of the esophagus and can also be left in place if it is elected to leave the endotracheal tube in place at the conclusion of the operation. Once it is confirmed that the NG tube is in the stomach, either by aspiration of gastric contents or by intraoperative palpation, it is our practice to instill 100cc of cream spiked with an ampule of methylene blue. This is to allow for the detection of any chyle leak during the operation, and allow for it to be repaired. The patient is then positioned in the appropriate lateral decubitus position and draped in a manner that will allow extension of the incision to the costal margin if necessary. All previous incisions should be marked and, if at all possible, incorporated into, and excised with, the thoracotomy incision.

The previous incisions are incorporated as ellipses. The cutaneous ellipse is grasped in one hand and the deeper portion is palpated. If the biopsy track is palpable, then it is traced—with a margin—into the interspace and can be amputated at the pleural level or left en bloc to be removed with the main specimen. If there is no palpable abnormality, then the ellipse is taken as a full-thickness skin and subcutaneous fat specimen down to muscle.

There is a distinct advantage to minimizing trauma to the chest wall musculature with multiple excisions, particularly if the patient is going to have a pneumonectomy and require watertight closure of the chest wall. Occasionally patients may have had biopsies through one or several incisions that cannot be incorporated into any reasonable incision or which would require a degree of reexcisions that may compromise chest closure. If there is high suspicion of tumor growth in the biopsy sites, then they need to be excised. If there is a question, or if it appears that resecting multiple incision sites could compromise chest closure, then specimens can be sent for frozen section analysis. In these situations we send the skin and subcutaneous tissue from the ellipse, with the question to be answered as to whether what is palpable is scar or tumor. Only if cancer is identified on the frozen section will we then follow the entire region of firmness through the chest wall musculature and remove the intercostal muscle in the region, leaving the skeletonized ribs. These soft tissue resections can, in fact, be quite sizable in order to resect back to normal-appearing tissue. Regardless, all excised tract sites should be marked with surgical clips for radiographic identification, should the final pathology reveal tumor and adjuvant radiation be indicated. Some groups preemptively radiate all incisions after surgery, but this is of unproven benefit at this time.

Our typical approach is to enter the chest through the sixth interspace, sparing and retracting the serratus anterior muscle, but dividing the latissimus dorsi. If there is enough room in the interspace to gain entry to the extrapleural plane then we will leave the seventh rib, typically shingling it posteriorly to provide sufficient exposure and ideally avoid rib fracture. If the hemithorax is contracted, with no appreciable interspaces, then we routinely resect the seventh rib and gain access to the extrapleural plane through the bed of the resected rib. Rarely, the sulcus will be so deep in a large patient that additional room is required. In those situations the seventh rib can be excised, even if it was possible to enter the extrapleural plane without rib resection. Some surgeons advocate elevating the chest wall and creating a flap large enough to make a counterincision in the ninth or tenth interspace. It is likely to result in more postoperative pain, but it is an option to keep in mind for a particularly difficult diaphragm dissection.

Radical Pleurectomy

General Approach and Strategy

Over the years the author has utilized multiple techniques in an attempt to develop a standardized approach to radical pleurectomy. What follows is a description of this procedure in its current iteration. The general strategy that has resulted in the most reproducible results involves mobilizing the entire cancer from the hemithorax, such that it is tethered solely to the lung, and then resecting the entire visceral pleura en bloc with the mobilized cancer. Understanding that every one of these cancers is different and the surgeon must, therefore, be flexible in the approach, the typical order of dissection is bony hemithorax, posterior mediastinum, superior mediastinum, anterior mediastinum, diaphragm, and lung.

Chest wall/posterior-superior mediastinal mobilization: The first step of the operation is to mobilize the tumor off the bony hemithorax, followed by the posterior and superior mediastinum. This initial portion of the operation is the same whether the surgeon is planning to perform a radical pleurectomy or extrapleural pneumonectomy. The extrapleural plane is identified and entered adjacent to the incision. It is developed bluntly as much as possible. Blunt finger dissection, working a broad front, causes cleavage in the correct plane. Sharp dissection is more likely to leave behind gross tumor. The argon beam coagulator is a good device for cauterizing the chest wall, from which capillary ooze can lead to significant blood loss. The chest wall is the safest portion of the operation and is a good chance for the surgeon to get a sense as to how the tumor interacts with the surrounding tissues. As the dissection is carried to the posterior reflection onto
the posterior mediastinum, the surgeon can follow the intercostal veins from the azygos or hemiazygos veins as they traverse the mediastinum to safely transition from the chest wall to the posterior mediastinum. On the right side, the surgeon must take care not to get behind the esophagus and on the left it is the aorta that must be left in place as the pleura is separated from its medial surface. In the superior mediastinum, it is the subclavian artery on the left and the vena cava on the right of which the surgeon must be mindful. It is often helpful to employ a 10 mm 30 degree video thoracoscope for supplemental vision during the dissection to assure that the correct plane is identified and maintained, especially in the apex of the chest as the thoracic inlet and most superior mediastinum are dissected. On the right side, the azygocaval junction is typically approached both superiorly and posteriorly, having followed the azygos vein. This is an area where a venous injury can occur if the wrong plane is entered.

### Anterior mediastinum

The anterior mediastinum is approached by sweeping off all pericardial fat in an anteroposterior direction, starting in the pericardiosternal recess. The surgeon must take care not to breach the anterior pleural reflection and enter the opposite hemithorax. This portion of the operation is highly variable. Occasionally, nearly the entire pericardium is covered with pericardial fat and removing this fat leaves the pericardium with a macroscopic complete resection. More commonly, the pericardial fat dissection gets the surgeon out of the anterior recess, but confronted with most of the pericardium directly involved with the cancer. Rarely, the tumor will separate, leaving normal-appearing pericardium. If that is not the case, then an attempt can be made to separate the layers of the pericardium, leaving the serous pericardium intact and resecting the fibrous pericardium en bloc with the cancer and mediastinal pleura. This is technically challenging, but often possible. If the pericardium is too extensively involved to achieve a macroscopic complete resection, then the surgeon has two options. If it is only a small area, then it can be resected and the surgeon may wish to sew in a prosthetic pericardial patch if it is maintained as the base of the fissure and what is often considered a best accomplished with absorbable sutures. Sometimes, especially if the inseparable tumor is a central island and there is sufficient laxity in the remaining debrided diaphragm, the area can be lifted away from the abdomen and undercut with a thick tissue stapler. Care, obviously, must be taken to assure there are no viscera caught in the stapler and this is readily done by palpation. The staple line must then be oversewn with absorbable sutures as the diaphragmatic muscle, comprising the staple line, can tear and result in a hernia. If there is extensive involvement of the diaphragm then it is resected, as it is during an extrapleural pneumonectomy, and reconstructed with a 2 mm Gore-Tex patch.

### Lung

At this point in the dissection the entire tumor is tethered solely to the lung. The anesthesiologist is asked to connect the operative lung to an alternative oxygen supply with an in-line stack of PEEP valves that will allow it to be held under positive pressure ranging from 10 to 30 cm water. The tumor is then sharply incised, extending through the visceral pleura. The plane between the undersurface of the visceral pleura and bare lung parenchyma is then developed. Initially this is best accomplished with forceps and fine scissors, until at least several millimeters beyond the incision have been liberated. At this point the edge can be better grasped and the bare lung parenchyma can be very gently retracted. Over the years, the instrument that has proved best suited for further developing the plane is a broad Cobb dissector. Initially there is often a torrential air leak when the visceral pleura is removed from the parenchyma but, literally, within minutes the leaks nearly abate if the plane was maintained at the interface of visceral pleura and parenchyma. It is also worth noting that the assistant should be cautioned about gentle suctioning at this point in the operation, as even the most ginger advance with a suction instrument can penetrate into the lung parenchyma when it is devoid of pleura. This will result in air leaks that do not seal very readily. Sometimes a cancer will be encountered where portions or even, rarely, the entire lung will not yield the subpleural plane. In these cases, the electrocautery can be used to open the plane that is visibly evident, but does not yield to simple sharp or blunt dissection.

The critical element in the lung dissection, and what is often considered a contraindication to lung-sparing surgery, is to remove the tumor from the fissures. This is safely accomplished by saving this part of the lung dissection for last. The cancer is tracked down into the fissure, following from both sides. An even level is maintained as the base of the fissure is approached. At this point the lung is deflated and the surgeon will be able to palpate the deepest portion of the fissure of which the cancer has formed a cast. In any patient with complete fissures, this will typically terminate on the surface of the interlobar pulmonary artery. Under direct vision, the vein-like investing tissue over the artery is sharply divided, thereby releasing the cancer from the fissure. This will often result in skeletonization of the pulmonary artery within the fissure (Fig. 29.1). Once the tumor is released in the fissure, the similar investing band of extrapleural tissue can be identified and divided around the hilum, thereby dividing the remaining...
attachments of the tumor to the patient. In cases where the cancer is pliable, a single large specimen may result (Fig. 29.2). Sometimes, however, the cancer may be so firm that in order to have enough room to work and still preserve the lung, the tumor is better removed piecemeal (Fig. 29.3).

Once the specimen is removed, the chest cavity should be inspected to assure that a macroscopic complete resection has been achieved. The video thoracoscope by providing light and magnification is very useful in helping to inspect all surfaces.

Lymphadenectomy: A thoracic lymphadenectomy is then performed dissecting all standard nodal stations. In addition, the author has been harvesting the posterior intercostal lymph nodes. The significance of these lymph nodes has not been definitively established and is an area of active investigation. For the purpose of our publications and analyses, given the lymph nodes are not described in any current staging schema, we have considered them as N1 lymph nodes as we have had multiple instances where these were the only positive lymph nodes. These nodes are accessed using the electrocautery to incise the posterior interspaces at the level of the rib heads. Often the nodes can then be bluntly delivered with a fingertip, like ejecting a pea from a pod, but sometimes it is necessary to reach into the interspace with a broad-tipped forceps. Care must be taken during this maneuver to avoid avulsing the intercostal vessels as the nodes are closely associated.

Postoperative care: Straight chest tubes are placed anteriorly and posteriorly and directed to the apex. If a fluted tube is not used, then additional holes should be cut to access air and fluid throughout the entire intrathoracic traverse of the tubes. A rongeur is helpful for making extra holes in the chest tubes, taking care to not cut more than a quarter the diameter of the tube to avoid kinking, and making sure the most proximal hole is cut through the radiopaque marker to assure all holes are intrathoracic. A right-angle tube or flexible fluted tube is also placed along the diaphragm, terminating in the posterior costophrenic recess. Depending upon standard criteria, as well as the surgeon’s sense of the need for positive pressure to maintain full lung expansion, the patient can either be extubated or remain intubated and on pressure mode ventilation at the end of the operation. There are usually significant endobronchial bloody mucoid secretions present at the conclusion of these procedures; so the patient should undergo a completion toilet bronchoscopy at the conclusion of the operation, and again prior to extubation if the patient remains intubated. If the patient is extubated, then each chest tube should be placed on 20 cm of suction or higher levels if the lung is not fully inflated on the postoperative chest X-ray. There is a premium on achieving full lung expansion using the higher suction since this will, counterintuitively, help the air leaks seal more quickly if visceral to parietal pleural apposition can be achieved. If the patient is left intubated, then usually –10 suction applied to the chest tubes is adequate and can be increased when the patient is extubated. Because of the air leaks, volume calculations on the ventilator are unreliable and the ventilator needs to be adjusted empirically, based upon blood gasses. Typically, patients are hypocarbic, presumably from air being sucked through the lungs like gills. Having all three chest tubes connected to separate collection devices will allow the surgeon to assess leaks and drainage in a more useful manner. If the tubes are still leaking after 2 days, then the suction can be decreased as long as the lung remains fully inflated. Once on water seal, the leaks tend to stop quickly. Tubes can then be removed per routine criteria. Despite the enormity of the initial leaks, persistent air leaks are rare.

Attention to postoperative nutrition and pulmonary toilet are the critical issues postoperatively. Because the patients will have a compromised diaphragm, even the most motivated patients may have trouble clearing their secretions and may require one or several bronchoscopies in the postoperative period. There should be a very low threshold to performing bronchoscopy for secretion management.

Extrapleural Pneumonectomy
Extrapleural pneumonectomy involves the en bloc removal of the parietal pleura, lung, diaphragm, and pericardium, with prosthetic reconstruction of the diaphragm and pericardium. This procedure almost certainly remains the most commonly performed operation for mesothelioma and enjoys both the greatest standardization and largest reported experience. Beyond these advantages over lung-sparing operations, it undoubtedly leaves behind less microscopic disease. It does, however, engender the additional morbidity and quality of life changes that result from pneumonectomy. The author does not currently perform this operation for mesothelioma and would reserve it...
for a patient with epithelial mesothelioma who is a surgical candidate, but has a tumor demonstrating invasion of major bronchial and/or pulmonary vascular structures. The author’s preference and confidence in lung-sparing surgery arises from the excellent clinical results that have been obtained using this technique in combination with intraoperative photodynamic therapy, and abandoning hemithoracic radiation as an adjuvant treatment. This intraoperative adjuvant treatment remains the subject of ongoing investigation and despite superior clinical results remains an investigational treatment, just like any other surgery-based approach to treating mesothelioma. Any surgery-based multimodal treatment that involves hemithoracic radiation, or an intraoperative adjuvant that might be injurious to the lung, will require an extrapleural pneumonectomy. Extrapleural pneumonectomy, like radical pleurectomy, should be performed only by surgeons who are comfortable with the operation and postoperative management of these patients and in centers with the appropriate resources and personnel.

The technique for extrapleural pneumonectomy is identical to that for radical pleurectomy for the bony hemithorax and superior and posterior mediastinum. Anteriorly, however, the pericardium is entered, allowing for exploration of the pericardial space and resection of the pericardium, which will ultimately be removed en bloc with the specimen. Once the pericardium is dissected to the level of the diaphragm, the diaphragm resection is commenced.

The diaphragm is then dissected by dividing the costal insertions and entering the plane between the diaphragmatic muscleature and the peritoneum. This plane is then developed with blunt dissection, often with sponge sticks, separating the two structures. On the right side, great care should be taken to identify and divide the inferior phrenic veins to avoid avulsing them from the vena cava. On the left side care should be taken to preserve the rim of the diaphragmatic crus that forms the esophageal hiatus so as to avoid abdominal visceral herniation.

Following completion of these maneuvers the specimen is tethered only by the pulmonary hilar structures. On the right side, the pulmonary artery and the superior and inferior pulmonary veins are divided intrapericardially. On the left side, due to its relatively shorter length, the pulmonary artery is divided at its emergence from the pericardium. The veins are divided intrapericardially, same as on the right side. The bronchus, as with any pneumonectomy, should be taken as close to the carina as possible.

The Brigham group, to which much credit must be given for reducing this operation to a science, has a technique for patch reconstruction of the diaphragm that allows for visceral swelling after intraoperative bicavitary heated chemotherapy. Another technique is to fashion and sew in a 2 mm polytetrafluoroethylene (PTFE) patch with heavy nonabsorbable sutures, sewing to the residual rim of diaphragm and pericardium, occasionally encircling a rib if possible. Every effort should be made to make the patch as taut as possible to avoid paradoxical motion during respiration and also to facilitate radiation if it is planned as an adjuvant therapy. If radiation is planned, this should be discussed with the radiation therapist preoperatively as marking the perimeter of the diaphragm, and even the patch itself, with surgical clips may be useful for radiation planning.

The pericardium is reconstructed with a patch, commonly PTFE, and should be fenestrated to avoid tamponade, though these holes seem to seal off and patches are commonly found adherent to the heart, even in the setting of tamponade when the recurrence presents as a malignant pericardial effusion. On the right side it is critical to leave the caval openings generous, bearing in mind that the mediastinum will shift mediawally when the patient is taken out of lateral decubitus position and caval compression could result. It is the author’s practice to be able to introduce one to two fingers through each caval opening.

It is prudent to buttress the bronchial stump after this operation. It is the author’s preference to harvest the remaining pericardial fat that typically remains in the pericardiosternal recess. This can be taken as a superiorly based graft and sutured over the stump. Care must be taken not to breach the anterior pleural reflection into the opposite chest. Often these grafts are meager, compared to a standard pericardial fat pad, and must be crafted to achieve sufficient length. If this is not possible, then an intercostal muscle can be harvested, but this further compromises the integrity of the chest wall closure and with these rapidly filling chest cavities the surgeon must be vigilant for a large incisional seroma formation, which can be difficult to manage and disastrous if there is a wound infection. The Brigham group enters the abdomen as part of their intraoperative adjuvant therapy. In this setting omentum, arguably the best buttress, should be harvested to cover the stump.

Depending on the surgeon’s routine and the available postoperative support, it is usually best, if extubation criteria are fulfilled, to remove the endotracheal tube in the operating room to avoid positive pressure on the bronchial stump. Another option is to change the double-lumen endotracheal tube to a single-lumen tube and leave the patient intubated overnight. When this option is selected, the patient is maintained on a short-acting sedative, like Propofol, and ventilated on a pressure-limited ventilation mode using the minimal pressures necessary to maintain adequate gas exchange. Unless oxygenation is an issue, PEEP does not need to be used. The patient can then be bronchosoped the following morning, secretions cleared, and then extubated after sedation is held and pain control is assured. If the patient had a pericardial reconstruction, it is prudent to maintain a supine position and allow for only minimal rolling for the first day. Otherwise, having the patient up and ambulating immediately is critical for pulmonary toilet.

Postoperatively it is the author’s practice to leave a single tunneled chest tube in place and connected to a balanced drainage collection system to monitor for bleeding, chyle leak, and to position the mediastinum. A single simple 3-0 monofilament stitch is placed through the center of the chest tube incision and left untied, to be tied when the tube is removed. The Brigham group has a routine for aspirating the pleural space through a red rubber catheter and then removing the tube. In either case, the surgeon must be cognizant and vigilant that both bleeding complications and chyle leak are more common after extrapleural pneumonectomy than a standard pneumonectomy. Even in the absence of a complication the hemithorax often fills much more rapidly after an extrapleural pneumonectomy than a standard pneumonectomy. For all of these reasons, the surgeon must be extra vigilant in following the postoperative chest radiographs and tension hydrothorax should be considered in the differential for a patient with rapid or insidious decompensation. The author tends to leave the tube in place until the drainage is clearly trending downward and, depending upon the size of the patient, is less than several 100 ml/day. This may take several days. Although controversial, it is our practice to maintain patients on antibiotics until the chest tube is removed and to instill a small volume of broad-spectrum antibiotics (such as several drops of Betadine) into the chest cavity just prior to tube removal. Otherwise, the postoperative care of the extrapleural pneumonectomy patient is similar to that of other pneumonectomy patients: adequate pain control, early and frequent ambulation, pulmonary toilet, and maintenance of a
relative state of dehydration until the threat of postpneumonectomy pulmonary edema has passed.

EDITOR’S COMMENTS

There are only a little over 3,000 cases of malignant pleural mesothelioma seen in the United States in any given year; thus the average surgeon likely will not see a case. As Friedberg points out this malignancy is best treated in centers that have an interest in the disease and are able to offer the full array of potential treatment options. The surgical procedures that he describes, with the exception of thoracoscopic biopsy, are perhaps best left for those surgeons who have a special interest and expertise in mesothelioma as he does. Prior to embarking on a treatment regimen the diagnosis of mesothelioma must be established with confidence and this usually means that tissue must be obtained as pleural fluid cytology only infrequently is able to yield an answer. Even with a tissue specimen at times differentiating mesothelioma from adenocarcinoma can be challenging. The use of tissue biomarkers may aid in confirming the diagnosis but no one marker has been shown to be the definitive one. An elevated level of serum fibulin-3 has been shown to be highly accurate in distinguishing those patients with malignant mesothelioma from those exposed to asbestos but without mesothelioma and from those with other malignancies or benign causes of pleural effusion. Currently, this serum biomarker has not been proven to be of value in the early diagnosis of malignant mesothelioma or for monitoring patients who have undergone therapy. Other potential biomarker candidates include osteopontin and mesothelin.

Patient selection appears to be the most significant determinant long-term outcome as those patients selected for a surgical-based multimodality approach tend to be those that have the highest likelihood of prolonged survival. These clearly are the “best” patients, that is those who are young enough to withstand a multimodality approach that involves a major operation, those with disease limited to a hemithorax, and those with favorable histology. Those patients who present with mesothelioma with pure epithelial elements are those who have shown long-term survival with resection. The sarcomatoid variants do poorly with any treatment and should rarely be candidates for resection and certainly not outside the confines of a rigorously designed investigational protocol. Attainment of a complete resection with negative margins is perhaps the most important determinant of long-term survival. Friedberg refers to this as removal of all gross macroscopic disease. I am somewhat surprised that Friedberg still considers patients with proven mediastinal nodal involvement as candidates for surgical resection.

As to whether radical pleurectomy can achieve as complete a removal of all gross macroscopic disease as well as extrapleural pneumonectomy remains to be determined in my opinion. I congratulate Dr. Friedberg on his attempts to define the optimal procedure to attempt to remove all gross disease while still retaining the lung. Clearly, if the lung can be saved while still achieving removal of all macroscopic disease the patient benefits by experiencing less morbidity and clearly a lower chance of mortality as compared to extrapleural pneumonectomy. In the best and most experienced hands the occasional perioperative death occurs following extrapleural pneumonectomy though this has clearly been attenuated based on the work done by the Brigham group.

Malignant pleural mesothelioma continues to produce significant therapeutic challenges made all the more difficult by the relative paucity of cases seen in any given year. As mentioned, these patients are best treated in centers that have a particular expertise and interest in the disease.

LRK
INTRODUCTION

An adequate pathologic assessment of lymph nodes draining the site of the primary tumor is an important oncologic principle in nearly all solid organ malignancies. Complete histologic evaluation of lymph nodes provides significant prognostic information for overall survival and disease-free survival. Additionally, the overall number of resected nodes has become a quality measure of the adequacy of surgical resection. Pathologic lymph node status (pN) is a crucial component of the tumor, node, and metastasis (TNM) staging system and influences clinical and therapeutic decisions in patients with nonsmall cell lung cancer (NSCLC). Although the survival benefit of lymphadenectomy has not been proven in randomized trials, it is possible that a select group of patients with truly loco regional disease might benefit from a meticulous lymph node dissection beyond the merits such a dissection would have for stage classification. A surgeon's role in this process is irreplaceable, as the performance of lymphadenectomy requires a thorough anatomic knowledge of lymph node basins draining the primary tumor site as well as a technical skill and judgment for safe accomplishment of this task.

ANATOMY AND CLASSIFICATION OF INTRATHORACIC LYMPH NODES

The prognostic importance of the metastases to regional lymph nodes in patients with lung cancer has been recognized for over 50 years. The first comprehensive classification of the thoracic lymph node stations has been developed by Naruke et al.; this Japanese classification was used worldwide for almost four decades. In the 1990s, the American Thoracic Society (ATS) attempted to refine the anatomical descriptions of thoracic lymph nodes and in 1997, Mountain and Dresler published a modification of the ATS lymph node map, which was later implemented into the American Joint Committee on Cancer (AJCC) and Union for International Cancer Control (UICC) Lung Cancer Staging System. While this revised form of lymph node stations has been widely adopted in the United States, it was only sporadically used by the European surgeons, and the Japanese continued to favor the original Naruke's classification. An effort to consolidate worldwide lung cancer staging data began in 1998 by the International Association for the Study of the Lung Cancer (IASLC) with the establishment of the Lung Cancer Staging Project. In this project, data from over 100,000 patients were collected. The discrepancies between Naruke and Mountain–Dresler thoracic lymph node maps became significant during data analysis as some patients with N2 (or stage IIIA) disease according to Mountain–Dresler classification were staged as N1 (or stage II) disease in Naruke classification. Consequently, IASLC published the third detailed anatomic classification of intrathoracic lymph node stations, reconciling the differences between former Japanese and American lymph node maps (Table 30.1). Fourteen discrete lymph node stations have been recognized, which are grouped into the following seven zones: supraclavicular (level 1 nodes), superior mediastinal upper zone (level 2, 3, and 4 nodes), aortic nodes/aortopulmonary zone (level 5 and 6 nodes), inferior mediastinal subcarinal zone (level 7 nodes) and inferior mediastinal lower zone (level 8 and 9 nodes), N1 nodes hilar/interlobar zone (level 10 and 11 nodes), and peripheral zone (level 12, 13, and 14 nodes; Fig. 30.1).

INTRATHORACIC LYMPHATIC FLOW AND METASTATIC SPREAD

The anatomical description of the mediastinal lymphatic flow may be credited to Riquet et al. who, in a meticulous post-mortem dissection utilizing dye injection of the lymphatics, identified intrathoracic lymphatic drainage pathways. The in vivo investigation of the thoracic lymphatic flow was later studied by Hata et al., who generated dynamic lymphoscintigrams by injecting ⁹⁹ᵐTc-labeled colloid into the segmental bronchial submucosa. He identified the following lobar and segmental lymphatic drainage patterns: Right lung: the apical and posterior segments of the right upper lobe drained via the hilar nodes (level 10), tracheobronchial nodes (level 4), and upper paratracheal lymph nodes (level 2) into the ipsilateral scalene nodes. Drainage from the anterior segment of the right upper lobe varied with approximately 50% of flow via subcarinal (level 7) lymph nodes into the right scalene nodes; occasionally, the lymph flow crossed the midline following the course of the innominate vein into the left scalene lymph nodes. The other half of the time the flow from the anterior segment resembled the flow the other segments of the upper lobe. Lymphatic drainage from the middle lobe and the superior segment of the lower lobe resemble the upper lobe drainage ultimately ending in the ipsilateral scalene nodes either via lower paratracheal or subcarinal nodes. Again, in a minority of cases the flow from the middle and lower lobes was noted to cross to the left scalene nodes via subcarinal and left lower paratracheal nodes. Left lung: Lymphatic flow from the left lung was variable; however, certain patterns were identified. The apical posterior segment of the left upper lobe drained primarily via the subcarinal lymph nodes along the left vagus nerve to the left scalene nodes or along the recurrent laryngeal to the paratracheal lymph nodes. The anterior and lingular segments drained along the left nerve through the para-aortic nodes (level 5/6) to the ipsilateral scalene lymph nodes. Lymph from the basilar segments flowed via the subcarinal nodes to the pretracheal and contralateral paratracheal lymphatics to the right scalene nodes. Drainage from the superior segment was least constant and occurred via multiple pathways. The study demonstrated mostly consistent ipsilateral lymph drainage along mediastinal lymph node stations with an occasional contralateral drainage.

A number of authors have studied the pattern of intrathoracic metastatic spread of lung cancer. Borrie initially demonstrated cancer occurrence along the bronchus intermedius on the right side and along the main fissure on the left; these lymphatic sumps are now referred to as the Sumps of Borrie.

In a study of 359 patients who underwent mediastinoscopy, scalene node biopsy and thoracotomy, Nohl-Oser identified the pattern of regional metastatic spread. Right upper lobe tumors had a propensity to spread to ipsilateral mediastinal nodes (75%); contralateral mediastinal or scalene node involvement was rare in both right upper and lower lobe tumors (<5% to 7%). Left upper lobe tumors, however, had higher incidence of contralateral involvement in mediastinal and scalene nodes (10% to 13%) as did left lower lobe tumors (14% scalene and 25% mediastinal).

Intrathoracic lymphatic involvement of biopsy-proven N2 disease was characterized by Asamura et al. in a study of 166 patients. Right upper and lower lobe tumors had much higher propensity to spread into the pretracheal and ipsilateral paratracheal nodes, whereas right middle lobe tumors had the highest association with subcarinal lymphadenopathy (88%). On the left side, metastatic disease was most consistently found in the aortopulmonary window and para-aortic nodes (levels 5 and 6). Involvement of subcarinal (level 7) nodes occurred in the fifth of patients, most frequently when a tumor involved the lingular segment. Metastatic disease from lower lobe tumors was found with almost equal frequency in the subcarinal and aortopulmonary nodes. Although these studies demonstrate

Fig. 30.1. IASLC nodal chart with stations and zones. (Reprinted courtesy of the International Association for the Study of Lung Cancer and with permission of Aletta Ann Frazier, MD.)
frequent orderly ipsilateral cancer spread from the intraparenchymal to hilar to paratracheal lymph node chains, skip metastases may occur in up to one-third of cases. The occasional drainage into the contralateral lymph nodes argues for a vigilant preoperative lymph node evaluation in patients with newly diagnosed lung cancer.

STUDIES CONCERNING LYMPH NODE DISSECTION

Sampling vs. Dissection

As mentioned previously, mediastinal lymphadenectomy is an important component of the surgical treatment of lung cancer. Importance of lymphadenectomy in accurate disease staging is self-evident; however, debate continues whether lymphadenectomy influences survival in lung cancer patients. Additional controversy in the resection and evaluation of mediastinal lymph nodes concerns sampling versus completely dissecting mediastinal lymph node stations. Previously, a randomized trial by Wu et al. demonstrated survival benefit for systematic nodal dissection in patients with resectable NSCLC; however, other randomized trials failed to show significant survival benefit. To further study the effect of mediastinal lymphadenectomy on survival in NSCLC, the American College of Surgery Oncology Group (ACOSOG) performed a multi-institutional prospective randomized trial (ACOSOG Z0030) to study the effect of mediastinal lymph node sampling (MLNS) versus complete lymph node dissection during pulmonary resection in patients with N0 or N1 (less than hilar disease) in NSCLC. The aim of this study was to compare the survival and recurrence pattern between the groups. Over a 5-year period (1999 to 2004), 1,111 patients were accrued into this randomized trial by 102 surgeons in 63 institutions. After excluding 88 patients, final intent-to-treat analysis was performed on 1,023 patients of whom 498 underwent MLNS and 525 who had mediastinal lymph node dissection (MLND). There were no significant demographic differences between the groups in tumor histology, Eastern Cooperative Oncology Group (ECOG) status, type, or completeness of resection. There was no difference in the median number of nodes removed by thoracoscopic technique or thoracotomy (15 vs. 19; \( P = 0.17 \)). More nodes were removed during lobectomy compared with segmentectomy (18 vs. 14; \( P = 0.006 \)). At a median follow-up of 6.5 years, there was no significant difference in the overall survival between the groups (\( P = 0.25 \)). Similarly, the 5-year disease-free survival was no different (68% in MLNS group and 67% in MLND group; \( P = 0.89 \)). Additionally, there were no differences found in local, regional, or distant recurrence between the two treatment arms. Authors concluded that lymph node dissection in and of itself does not improve long-term survival in patients with early stage T1 or T2 or non-hilar N0, N1 NSCLC who have pathologically negative mediastinal, or hilar lymph nodes after rigorous preoperative lymph node sampling. It must be emphasized that these data cannot be extrapolated to T3 or T4 tumors, or to patients with N2 lymph node disease. Interestingly, the authors recommended that all patients with resectable NSCLC should undergo MLND, since complete nodal dissection does not increase morbidity or mortality but significantly aids in accurate pathologic staging.

Number of Lymph Nodes Harvested during Lymphadenectomy

To achieve maximum information about a given malignancy, histopathologic evaluation has to contain not only the description of the primary tumor but also the examination of resected lymph nodes. While complete lymphadenectomy is recommended for the treatment of lung cancer, what constitutes complete lymph node dissection is not well defined. The number of harvested lymph nodes has become a measure of the quality of surgery for certain tumors, such as colorectal cancer where a minimum of 12 lymph nodes have to be resected in order for the procedure to be considered adequate. In other malignancies (stomach, esophagus, lung), this number is not as clearly defined. Principally, the more lymph nodes examined the stronger the validity of tumor staging and less potential for stage migration effect. Data regarding the recommended number of harvested lymph nodes in NSCLC are derived either from retrospective studies or from consensus conferences. Current recommendation is for the removal of a minimum of six lymph nodes from mediastinal and hilar stations with at least one subcarinal lymph node. However, some authors recommend at least 10 lymph nodes from three nodal stations.

As part of the ACOSOG Z0030 trial, authors analyzed the yield of examined lymph nodes from each lymph node station, the frequency of obtaining at least one lymph node from a station, and the frequency of occult N2 disease by lymph node sampling and dissection. Lymph node sampling was performed in 555 patients, dissection in 556; final analysis was performed in 498 patients with sampled nodes and 524 with dissected nodes. Overall, a median of 18 lymph nodes were resected per patient for both left- and right-sided cancers. The median number of nodes from N1 stations was 5 for right-sided and 6 for left-sided tumors (\( P = 0.134 \)). A median 3 nodes were harvested from subcarinal (level 7) station and 4 from 4R station. At least six lymph nodes were resected in 99% of patients with 90% of patients having more than 10 nodes resected from three lymph node stations. Four percent (\( N = 21 \)) were found to have occult N2 disease, which was not identified by the rigorous pretreatment nodal sampling. While the majority of nodes were harvested at thoracotomy with only 29 patients having thoracosopic lymphadenectomy, there was no difference in the number of harvested nodes. As expected, the number of harvested nodes was not associated with tumor type, age, or gender. Most importantly, an increase in N stage (upstaging) was noted with more thorough lymph node harvesting (\( P = 0.043 \), supporting the concept of systematic lymphadenectomy in accurate staging. The argument for comprehensive lymphadenectomy and thus accurate pathological staging is further underscored by the demonstrated survival benefit of adjuvant chemotherapy in stage I to III patients in the International Adjuvant Lung Cancer Collaborative Group Trial (IALT). Lung Adjuvant Cisplatin Evaluation (LACE), a meta-analysis of five largest randomized trials of adjuvant chemotherapy, also demonstrated improved survival in stage II and III patients.

Lymphadenectomy via Thoracoscopy vs. Thoracotomy

With the increasing use of video-assisted thoracic surgery (VATS), the question arises whether the efficacy of MLND is the same with VATS as with thoracotomy. D’Amico et al. utilized National Comprehensive Cancer Network’s NSCLC Database to compare the adequacy of MLND during lobectomy by thoracotomy and VATS with respect to the number and location of all N1 and N2 lymph node stations resected or sampled; at least three lymph node stations had to be sampled or resected to be included in the analysis. The number of N2 lymph node stations and a total number of lymph nodes N1 + N2 were also compared. Over a 3-year study period, they identified 4,215 patients with a new diagnosis of NSCLC of which 851 underwent lobectomy for stage I to III
disease. Final analysis was performed on 388 patients of whom 199 had VATS and 189 open lobectomy. There were no significant differences between groups in patients performance status, Charlson comorbidity score, tumor histology, utilization of positron emission tomography, or mediastinoscopy; however, VATS resection was more prevalent in patients with stage I disease ($P = 0.002$). The assessment of mediastinal lymph nodes was equivalent in both groups (median 3; $P = 0.12$). Similarly, the assessment of N2 lymph node stations was similar between thoracotomy (mean 2.91) and thoracoscopy (mean 3.15) groups. Moreover, the total number of N1 + N2 lymph node stations sampled was no different ($P = 0.06$). The authors concluded that mediastinal lymph node assessment of N2 lymph node stations was similar between thoracotomy and thoracoscopy; however, VATS resection was more prevalent in patients with stage I disease ($P = 0.002$). The assessment of mediastinal lymph nodes was equivalent in both groups (median 3; $P = 0.12$). Similarly, the assessment of N2 lymph node stations was similar between thoracotomy (mean 2.91) and thoracoscopy (mean 3.15) groups. Moreover, the total number of N1 + N2 lymph node stations sampled was no different ($P = 0.06$). The authors concluded that mediastinal lymph node assessment of N2 lymph node stations and combined N1 + N2 stations in patients who underwent thoracoscopic lobectomy was as effective as in patients who underwent lobectomy via an open thoracotomy approach. The study did not evaluate other oncologic outcomes such as local, regional, or distant recurrence, or survival. Table 30.2 summarizes studies comparing the effectiveness of nodal harvest utilizing thoracotomy and thoracoscopy.

### Survival and Local Recurrence

Whether mediastinal lymphadenectomy improves survival or local recurrence in patients with NSCLC remains an area of controversy. Wright et al. conducted a meta-analysis of randomized controlled trials to evaluate the influence of surgery in NSCLC. A pooled analysis of mortality over the first 4 years was made from three trials. While none of the individual trials found a significant difference in survival between the node dissection and sampling groups, the meta-analysis identified a significant reduction in the risk of death (HR 0.78; $P = 0.005$) in the group who had complete MLND. Ultimately, the definitive answer for this question may be difficult to achieve, since most studies are limited by small numbers of patients, differences in surgical technique, and adjuvant treatment algorithms. The Will Rogers phenomenon (the stage migration effect) is probably the most significant factor influencing patients’ survival. The benefit of complete lymphadenectomy likely varies in patients with NO, N1, and N2 lymph node status. Hypothetically, patients with negative nodes (NO) should not derive any benefit from lymphadenectomy, whereas others (N2) may benefit from more accurate staging and recommendations for adjuvant therapy. In patients with N1 disease and limited N2 disease, there is a likelihood that lymphadenectomy not only improves staging accuracy but has also a therapeutic effect.

The theoretical argument that performing less than a complete mediastinal lymphadenectomy during lung cancer surgery might leave cancerous cells behind in nonresected lymph nodes has lead to concerns regarding whether lymph node sampling might lead to higher rates of local recurrence. Lardinois et al. studied the effect of lymph node dissection versus sampling on local recurrence in 100 patients with stages 1 to 3 who underwent R0 resection. Local recurrence was observed in 40% of patients who underwent nodal sampling versus 16% of patients who underwent dissection. Higher local recurrence was seen after sampling in both stage 1 (45% vs. 13%; $P = 0.02$) and stage 2 (55% vs. 17%; $P = 0.09$) patients; stage IIIA patients had nonsignificant difference in local recurrence between the groups. In patients with pathologically node-negative mediastinal nodes (NO and N1 patients), observed local recurrence was 46% after sampling compared with 13% after dissection ($P = 0.004$). This study, however, was nonrandomized and nodal dissection or sampling was at the discretion of an individual surgeon. The ACOSOG Z0030 randomized trial did not demonstrate increased local recurrence in patients who underwent nodal sampling.

### Morbidity and Mortality of Mediastinal Lymphadenectomy

One of the arguments regarding MLNS versus complete nodal dissection involves a potential increase in morbidity and/or mortality caused by MLND. A greater theoretical potential exists for injuring the mediastinal vascular structures, nerves, and tracheobronchial tissue during systematic nodal dissection; this may result in increased chest tube drainage or hospitalization.

The trial ACOSOG Z0030 evaluated morbidity and mortality associated with MLND compared with lymph node sampling of two comparable groups of total 1,100 patients with T1 and T2 disease. The median estimated blood loss was the same between the groups (200 ml); however, the median operative time was 15 minutes longer in the dissection group ($P < 0.0001$), as was the total chest tube drainage (1,459 ml vs. 1,338 ml; $P = 0.056$). These small differences are unlikely to be clinically significant.

Table 30.2 Summary of Trials Comparing Nodal Harvest via Thoracotomy and VATS
and indeed, there was no difference in either chest tube duration or median length of stay between the groups. Similarly, there was no difference in rates of postoperative atrial arrhythmias, pneumonia, chylothorax, myocardial infarction, recurrent nerve injury, or bronchopleural fistula. Overall, operative mortality was 1.37% and was similar for sampling (2%) compared with dissection (0.76%; $P = 0.157$). This large, prospective, multi-institutional randomized study, which established modern benchmarks for thoracic surgery, effectively disproved the notion that complete mediastinal node dissection was more morbid than nodal sampling.

**MEDIASTINAL LYMPH NODE DISSECTION**

**Right-Sided Lymphadenectomy**

The principles of mediastinal lymphadenectomy are the same for both open and thoracosopic techniques. The goal of right-sided MLND is to remove nodes from stations 2R, 4R, 7R, 8R, and 9R—lymph nodes 10R to 14R are usually removed during lobar resection. Dissection of level 2R and 4R lymph nodes begins with opening of the mediastinal pleura midway between the right border of the superior vena cava (SVC) and the right vagus nerve, extending the incision from the superior aspect of the azygos vein, cephalad, to the level of the right subclavian artery. Lymphatic tissue is grasped and carefully dissected away from the right anterolateral aspect of the trachea taking care to avoid the right recurrent laryngeal nerve as it courses around the right subclavian artery (Fig. 30.2). The nodal packet is then retracted posteriorly and bluntly dissected away from the right side of the SVC. One should be aware of the existence of small venous branches from the posterior aspect of the SVC, which can easily be avulsed and should be divided between clips when present. Full mobilization of the azygos vein enhances the ability to dissect all nodal tissue medial to the azygos-SVC junction. A thorough dissection of the right paratracheal stations involves removal of nodal tissue to the left of the midline of the trachea. Care must be exercised in this regard as it is possible to injure the left recurrent laryngeal nerve if the dissection is overaggressive. After the removal of the level 2 and 4 nodes, dissection may be carried underneath the azygos vein anterior to the right main pulmonary artery and right mainstem bronchus, this allows dissection of the level 10R nodes. The exposure of the subcarinal (level 7) lymph node basin begins with opening the mediastinal pleura from the inferior border of the azygos vein, across the right mainstem bronchus, posterior to the hilum and inferiorly to the level of the inferior pulmonary ligament, which is fully mobilized; the lung is retracted anteriorly (Fig. 30.3). Level 7 nodes are in a close relationship with the inferomedial aspect of the right and left mainstem bronchi of the esophagus, and posterior aspect of the pericardium. The arterial supply to the level 7 nodes comes from the right (usually one) and left (usually 2) bronchial arteries, which usually traverse the anterior aspects of the mainstem bronchus. Dissection usually begins on the inferior border of the lymph nodes allowing the entire packet to be elevated off the pericardium. Posterior retraction of the esophagus allows further development of the plane between the nodal packet and the esophagus. Dissection proceeds along the inferior border of the right main bronchus.
to the level of the carina. At this point, the vascular supply to the nodal packet should be searched for and clipped or ligated before dissecting the nodes away from the carina (Fig. 30.4). Grasping lymph nodes with a ring forceps allows retraction of the entire lymphatic chain, which is commonly removed en bloc. Vagal branches to the lung may be divided and usually may transiently stimulate the cough reflex. Further hemostasis may be achieved with gentle packing with or without hemostatic agents such as Surgicel® (Ethicon, Inc., a Johnson & Johnson company, Somerville, NJ) or thrombin with gelfoam. Full mobilization of the inferior pulmonary ligament exposes nodal stations 8 and 9. Level 9 nodes lie within the ligament and are readily removed. Level 8 nodes found in the periesophageal space are likewise dissected free and removed avoiding the injury of the main trunk of the vagus nerve. Nodes anterior to the SVC (3a) and posterior to the trachea (3p) are not routinely removed as part of a right-sided MLND but should be excised if enlarged or suspicious on preoperative imaging studies.

**Left-Sided Lymphadenectomy**

Left-sided mediastinal lymphadenectomy removes nodal stations 4L, 5L, 6L, 7L, 8L, and 9L. Starting just below the thoracic inlet, the mediastinal pleura is incised posteriorly to the left subclavian artery. The subclavian artery is retracted anteriorly to expose the trachea. Left paratracheal lymph nodes (level 2) are grasped with ring forceps and dissected free. Care is taken to preserve the left vagus nerve running medial to the subclavian artery with the left common carotid artery and descending anteriorly onto the aortic arch below, which the recurrent laryngeal nerve branches and ascends in the tracheoesophageal groove superiorly (Fig. 30.5). Next, with the lung retracted inferiorly, the mediastinal pleura anterior to the aortic arch and parallel to the vagus nerve is incised superiorly exposing the level 5 nodal basin posterior to the ligamentum arteriosum between the aortic arch and left pulmonary artery. While keeping the left recurrent laryngeal nerve protected, these nodes are grasped and dissected free. Level 6 nodes, anterior to the ligamentum arteriosum and medial to the vagus and recurrent nerve, are then swept superiorly with the periaortic fibrolymphatic tissue. Removal of level 5 and 6 nodes allows the superior retraction of the aortic arch and inferior retraction of the left main pulmonary artery exposing the inferior aspect of the trachea; this facilitates dissection of the level 4 lower paratracheal lymph nodes. With esophagus retracted posteriorly and lung anteriorly, the subcarinal space is exposed by extending the pleural incision from the inferior border of the aortic arch to the inferior pulmonary vein, posterior to the hilum. Subcarinal level 7 nodes are removed beginning along the medial border of the left mainstem bronchus continuing inferiorly and crossing the medial aspect of the right mainstem bronchus. Lymphatic tissue is dissected free from the pericardium posteriorly. At the level of the carina, bronchial arteries are ligated and further hemostasis is obtained with judicious use of cautery or gentle temporary packing. Inferiorly, the left pulmonary ligament is incised and level 9 nodes are readily ligated together with level 8 paraesophageal lymph nodes.

**Fig. 30.4.** The subcarinal nodes are supplied by branches from the bronchial arteries, which should be clipped during dissection.

**Fig. 30.5.** Anatomic relationships of the left phrenic nerve, left vagus, and recurrent laryngeal nerves to the left main pulmonary artery and aortic arch.
SUGGESTED READINGS

Though the procedure itself may not be therapeutic, there is no question that a systematic mediastinal lymph node dissection as part of any operation for nonsmall cell lung cancer provides the optimal staging information. With no additional morbidity resulting from mediastinal node dissection, there really is no reason simply to perform nodal sampling. The systematic dissection requires little additional effort and results only in a couple of minutes of additional operating room time. And for certain stage disease node dissection ultimately may prove to be of therapeutic value. The authors have done a beautiful job of laying out the data supporting mediastinal lymph node staging and describing how the procedure should be accomplished. A lobectomy without complete lymph node staging to include both N1 and N2 nodes is an incomplete operation and leaves many questions unanswered. Despite that knowledge, there are still many pulmonary resections performed today that do not include assessment of the mediastinal lymph nodes.

Mediastinal lymph node dissection on the right side results in the removal of a nicely contained nodal packet since the superior mediastinal compartment, bordered by the subclavian artery superiorly, the trachea posteriorly, the superior vena cava anteriorly, and the azygos vein inferiorly, is so nicely defined. The same cannot be said for the left side where the level 5 and 6 nodes are removed separately in addition to the level 2, 4, and 7 nodes. It is actually easier, and probably more effective, to assess the left paratracheal and tracheobronchial angle nodes with mediastinoscopy. Approaching the left paratracheal lymph nodes at thoracotomy requires dissection in the aortopulmonary window potentially putting the left recurrent nerve at risk of injury. It should also be noted that a mediastinoscopy does not obviate the need to remove other nodes from the left side or to complete a lymph node dissection on the right.

To achieve the most accurate staging information, it is critically important for the surgeon to precisely label lymph nodes so the pathology report may be correctly interpreted. I find it optimal to label nodes according to the level based on the IASLC map so there is no question as to the location or whether or not a given node is N1 or N2.
Empyema, or empyema thoracis, can be defined as a purulent fluid collection in the pleural space. The etiology is varied and includes contamination from adjacent organs, most commonly the lungs, or direct inoculation by trauma or iatrogenic interventions. It is an ancient disease that often requires therapy that harkens back to ancient times.

**HISTORY**

Empyema thoracis was first described in the 5th century BC by Hippocrates. He wrote that the most common cause was the entrance of foreign bodies into the lungs, either by inhalation or drinking. They may also be caused by parapneumonic effusions if the chest is not cleared by expectoration within 14 days. Symptoms were described as fever, rigor, and thoracic pain and signs included copious sweating, cough, red eyes, bent nails of the hands, and anorexia. On physical examination, Hippocratic physicians asked patients to sit on a chair and then shook them. By placing their ears to the chest wall (immediate auscultation), they could hear a typical rippling sound, similar to that produced by a bottle half-filled with fluid. If no sound was heard, the empyema was noted on the side of the chest that was more swollen and painful.

Management was conservative initially, with the application of plant roots and honey as well as physiotherapy in the form of warm baths and inhalation of vapors with subsequent shaking of the patient to achieve eruption and expectoration of the pus. If this failed, then surgery was pursued. "First, cut the skin between the ribs with a bellied scalpel; then wrap a lancet with a piece of cloth, leaving the point of the blade exposed a length equal to the nail of your thumb, and insert it. When you have removed as much pus as you think appropriate, plug the wound with a tent of raw linen, and tie it with a cord; draw off the pus once a day; on the tenth day, draw all the pus, and plug the wound with linen. Then make an infusion of warm wine and oil with a tube, in order that the lung, accustomed to being soaked in pus, will not be suddenly dried out. When the pus is thin like water, sticky when touched with a finger, and small in amount, insert a hollow tin drainage tube. When the cavity is completely dried out, cut off the tube little by little, and let the ulcer unite before you remove the tube (Papavramidou)."

This remarkable treatise on the management of empyema with open tube drainage as its hallmark defined the standard of care for the disease for more than two millennia. During the world influenza pandemic of 1918 to 1919, there was a crisis. Draftees in crowded military camps were particularly susceptible to the streptococcal pneumonia and empyema that often accompanied influenza. A survey by the Surgeon General of the Army found a mortality rate of 30% for empyema drainage at base hospitals with deaths frequently occurring within 30 minutes of the procedure. This prompted the appointment of Major Evarts A. Graham to head a commission to study the problem. Dr. Graham cautioned against early drainage due to the risk of open pneumothorax and advocated operation only after the development of frank pus as this is usually accompanied by an abscess isolated from the remaining pleural cavity. He also recommended closed drainage rather than open drainage. Adoption of these changes to practice decreased the mortality rate to close to 5%.

**CLASSIFICATION**

Empyema follows a natural progression that has been classified by the American Thoracic Society into three distinct stages. In the exudative stage, or acute phase, the inflamed pleural membranes swell and discharge a thin effusion with associated bacterial contamination. The fluid is clear and has a low cell count. As the disease progresses to the fibrinopurulent stage, or transitional phase, deposition of fibrin occurs resulting in loculation formation and turbid, or frankly purulent, fluid. In the final stage, the organizing or chronic phase, in-growth of fibroblasts, and associated collagen fibers render the lung trapped and relatively functionless.

**ETIOLOGY**

As mentioned above, empyemas generally result from either contamination from a contiguous septic organ or direct inoculation during trauma or iatrogenic maneuvers. The most common cause is parapneumonic. Other contiguous sources include esophageal ruptures, deep cervical abscesses, paraspinal infections, and subphrenic collections. Rarely, hematogenous spread from distant sources can result in empyema, particularly in the immunocompromised population.

Post traumatic empyemas are associated with either penetrating injuries or the presence of a hemotorax. As the hemothorax represents an ideal growth medium for bacteria, any instrumentation of the chest cavity, particularly in less than ideal conditions, increases the risk of development of an empyema. Chest tubes inserted in nonsterile conditions, multiple reinsertions of chest tubes, excessive manipulations of chest tubes, residual blood from incompletely evacuated hemothoraces, and prolonged drainage are factors all associated with the development of empyema. Other factors in blunt trauma associated with empyema include the presence of a hemopneumothorax, suggestive of parenchymal injury and ongoing bacterial contamination of the pleural space.

Iatrogenic causes of empyema range from minor interventions, such as needle biopsies and thoracentesis, to postoperative occurrence following lung or esophageal surgery. The management of a postpneumonecomy empyema with or without associated bronchopleural fistula is particularly challenging.

**BACTERIOLOGY**

The spectrum of causative organisms of empyema varies somewhat with geography; hence, local data are often required to guide
therapy. In developed countries, the most common organisms isolated in adult community acquired empyema are *Streptococcus milleri*, *Streptococcus pneumoniae*, and anaerobes. In hospital-acquired empyema, *Streptococcus aureus*, including methicillin-resistant *S. aureus* (MRSA), is the most commonly isolated organism. In pediatric empyema, the most common organism is *S. pneumoniae*.

**COMPLICATIONS**

The complications of empyema occur with increasing likelihood as the disease progresses, with the majority developing in the chronic or organizing stage. Pulmonary fibrosis due to increased scar tissue within the lung and pleura can develop. Similarly, scarring of the chest wall and intercostal muscles can lead to contraction. Complications associated with local drainage may occur as well as the infection follows a path of least resistance to suppuration. Contiguous contamination can result in a myriad of complications. In the pursuit of the path of least resistance to suppuration, patients can develop empyema necessitatis with drainage through the skin. Alternatively, the infection can travel to the lung parenchyma, resulting in bronchopleural fistulae. Similarly, mediastinitis, pericarditis, subphrenic abscesses, and osteomyelitis of the ribs or vertebrae can develop.

**RADIOLOGY**

Radiological investigations facilitate diagnosis, enable planning of therapeutic approaches, and allow monitoring of progress. Ultrasound of the thoracic cavity can demonstrate septations and loculations and assist in making thoracentesis safer. Chest radiography is the first step in the evaluation of any suspected pleural pathology. Computed tomography (CT) is also very valuable in patients who do not have simple effusions. It permits visualization of the precise location of loculations, which can be helpful at the time of surgery, particularly with minimally invasive approaches.

**MANAGEMENT**

The goals in the management of empyema are to evacuate the infected material and insure re-expansion of the lung parenchyma with no residual space. The thoracic surgical adage, "No space, no problem" is particularly helpful to keep in mind in managing this disease process. A residual space will serve as a nidus of infection; hence, it needs to be obliterated. The earlier the intervention in the course of the disease process, the less invasive it needs to be. In the acute or exudative phase, simple drainage with even small-bore catheters along with appropriate antibiotic therapy will often be adequate. As the disease progresses to the fibrinopurulent or transitional phase, the development of loculations and adhesions makes complete drainage with simple small-bore catheters less likely to be successful. Figure 31.1A and 31.1B demonstrates a transitional phase empyema. There are no apparent loculations, but the CT images suggest that there is some sequestration of fluid and early fibrin deposition. In this setting, larger tubes or concurrent administration of fibrinolytics may be helpful, particularly in patients who are too unwell to tolerate general anesthesia.

The location of the empyema also plays a role. Collections that are posterior or paravertebral are particularly difficult to drain adequately via the percutaneous route. The narrow size of the intercostal spaces in the paravertebral location makes the placement of large-bore thoracostomy tubes difficult and uncomfortable. Similarly, collections adjacent to the mediastinum are also difficult to address percutaneously, as seen in Figure 31.2. Often these patients are better served by early video-assisted thoracoscopic surgery (VATS) drainage as are those whose loculations are so complex that adequate drainage is not able to be performed percutaneously (Fig. 31.3A and 31.3B).

The chain of intervention from least to most invasive then proceeds from small-bore catheters to chest tubes to VATS evacuation and decortication to thoracotomy for decortication to open window thoracostomy.

---

**Fig. 31.1.** (A) Axial computed tomographic mediastinal windows. Heterogenous density of fluid, suggestion of fibrin deposition. (B) Coronal computed tomographic mediastinal windows. No rind visible on visceral pleura.
TUBE THORACOSTOMY

When considering chest tube or intercostal catheter placement, the first principles of drainage should be adhered to, that is, that the drainage be prolonged, adequate, and dependent. There is some controversy in terms of the size of catheter that should be used for initial management of empyema. Frankly, this discussion generally takes place among respiratory physicians or pulmonologists, but it behooves the surgeon to be aware of the research that is taking place in this forum. Although there is no randomized data comparing small-bore to large-bore catheters in the management of loculated empyema, results from the Multicenter Intrapleural Streptokinase Trials (MIST) did collect data on the size of the catheters placed. They reported no significant difference in the frequency of surgery or the mortality based on the size of the catheter placed (from <10F to >20F). It should be noted that the choice of size of the catheter placed was at the discretion of the treating physician and that those that had the largest tubes placed had more frank pus and higher lactate dehydrogenase levels.

With increasing numbers of small-bore catheters being placed by interventional radiologists, and often with multiple catheters being used to evacuate separate loculations, it may be that improvements in the placement of the small-bore catheters are rendering them as good as large-bore catheters and the trend is for many physicians to advocate their usage. It makes intuitive sense that multiple well-placed small catheters can manage the empyemas that would have been managed with a large-bore catheter. And as demonstrated in the MIST study, there is no change in the number of patients that still require surgical intervention.

FIBRINOLYTICS

As noted above, the MIST trial was a double-blind randomized study of 430 patients. It showed that the administration of intrapleural streptokinase did not reduce mortality or the need for surgical salvage. This evidence for lack of benefit has led to other studies using other agents. The most recent reports focus on the concurrent administration of tissue plasminogen activator (t-PA) and DNase used together. A randomized trial reported that concurrent use of these two agents decreased the surgical referrals and the hospital stay as compared with placebo. This may influence the future management of early empyema as this combination of agents becomes more readily available.

DECORTICATION—OPEN VS VIDEO-ASSISTED THORACOSCOPIC SURGERY

If simple drainage and antibiotic therapy fail to control sepsis, then surgical intervention is warranted. The choice of operation depends on the stage of the empyema, the underlying condition of the patient, and the competencies of the surgeon. The goals of the operation remain evacuation of infected material and obliteration of the pleural space by rendering the visceral and parietal pleural layers in juxtaposition. A decortication consists of removing the infected material and freeing the lung parenchyma from the thick rind that often develops on the visceral pleural surface. This latter aspect of the operation is critical. Failure to re-expand the lung to fill the thoracic cavity will almost certainly result in persistent or recurrent sepsis. In addition, decortication always results in air leak from damage to the lung parenchyma when establishing and remaining in the correct plane to separate the rind from the visceral pleura. With complete lung expansion and chest tube drainage, the air leak will resolve in short order with minimal cause for concern. However, air leak in the setting of a persistent space will perpetuate the air leak and further contributes to ongoing sepsis and likely will mandate re-operation.

The surgical principles of decortication remain the same, regardless of approach (open or VATS). The infected material needs to be evacuated, the adhesions of the lung to the chest wall, mediastinum, and diaphragm need to be taken down, and the underlying lung parenchyma needs to have the thickened pleural rind removed enabling expansion of the lung, allowing it to fill the hemithorax and obliterate any residual space. The last steps should be copious irrigation before careful placement of drainage tubes. These steps were traditionally performed through an open procedure. At thoracotomy, intermittent ventilation of the operative side facilitates decortication as the inflated lung parenchyma provides gentle countertraction to the surgeon’s instruments. A combination of blunt and sharp dissection is required. We have found the use of “peanuts” and Cobb elevators to be very useful in establishing the appropriate plane of dissection. As a last resort, criss-crossed incisions, as seen on a well-cured and smoked ham, can be made into the thickened visceral pleura to enable lung expansion.

In the early days of VATS, many thoracic surgeons felt that a true decortication could not adequately be performed by this method if there was a thick rind trapping the lung. With increasing experience in VATS techniques, 30-degree cameras, and cooperation with our anesthesiology colleagues, many surgeons now perform the vast majority of their decortications via VATS technique. The advantages are clear.
These patients are often compromised and the recovery from VATS is clearly more rapid than with a thoracotomy. The main disadvantage is that the operation is often tedious and time-consuming. While generally performing VATS without lung isolation is impossible, it is the very rind that traps the lung that enables VATS decortications to be performed with the aid of intermittent ventilation of the operated side. While the lung is being ventilated, gentle blunt dissection with endoscopic elevators and “peanuts” or sharp dissection with scissors enables the removal of the peel. As in open surgery, key maneuvers include dissecting the lower lobe completely free of the diaphragm and dividing all adhesions circumferentially. Irrigation can often be performed early in the operation to facilitate exposure. Mechanical pulse lavage systems can be helpful in this regard.

In a comprehensive review comparing VATS to open decortication and to chest tube drainage alone for empyema, the authors evaluated 68 articles and chose 14 as providing best evidence for practice. They found that VATS offers superior outcomes to chest tube drainage alone and equivalent outcomes to open surgery. Moreover, they found that VATS decreases hospital stay, postoperative complications, and patient morbidity as compared with thoracotomy. The suggestion was that VATS should be considered before thoracotomy in patients requiring decortication.

**SPECIAL CIRCUMSTANCES**

Patients who have failed conservative management but are too unwell to tolerate general anesthesia present unique challenges. In these patients, long-term drainage needs to be established. One option is a well-placed large-bore chest tube. If the tube has been in place for 1 to 2 weeks, the lung should be fixed in position to the chest wall and that enables conversion of the closed drainage system to open drainage. Gradual removal of the chest tube, 1 to 2 cm a week, can be performed with the resulting cavity in the chest closing around the tube. In certain settings, a rib resection can be performed to enhance placement and long-term comfort of these empyema tubes. Another option is to perform an open-window thoracostomy by removing multiple ribs in the posterior and dependent portion of the hemithorax. Again, this can only be performed when the surrounding lung has adhered to the chest wall and is not in danger of collapse but this adherence is facilitated by the inflammatory process that results from the intrapleural infection.

In the post lung resection setting or in any situation where a residual space in the hemithorax exists due to underlying structural lung disease, it is important to achieve the goal of space obliteration. This can be accomplished by transposition of vascularized tissue into the thoracic cavity. Various chest wall muscles have been used for this depending on the location of the space in the hemithorax and the previous surgery performed. Serratus anterior, latissimus dorsi, and pectoralis major are good candidate muscles as long as they can be mobilized on their pedicles to the appropriate area. Greater omentum has also been reported with success when transposed through the esophageal hiatus or an enlarged foramen of Morgagni.

**SUMMARY**

Empyema thoracis has been well described for millennia. In addition to antibiotic and supportive management, the treatment
principles are twofold—evacuation of infected material and re-expansion of the lung with complete obliteration of any residual space. In early stages, this can often be accomplished by tube thoracostomy alone. In later stages, this surgical intervention likely will be required.

**SUGGESTED READINGS**

**EDITOR’S COMMENTS**

If there is one take-away message from this chapter it must be that in matters of the chest, space is the enemy. Especially in the situation of an empyema not only must the infected fluid or the pus be evacuated but any residual space must be obliterated or surely infection will recur. Draining an infected collection early potentially avoids the need for more invasive procedures as the authors point out. If recognized early, it is perfectly appropriate to place small pigtail catheters under radiographic guidance as long as they affect complete drainage. In these early infected collections ordinarily, there is no problem with complete lung re-expansion that adequately fills the pleural space. For the more organized collections where thick pus is present, a large bore thoracostomy tube clearly is the treatment of choice but the tube must be positioned so that complete drainage occurs. Depending on the appearance on the chest radiograph “blind” chest tube insertion may be less valuable than proceeding with a VATS drainage procedure with precise tube placement.

The more difficult problem is the management of a residual space with incomplete lung expansion and making the decision as to whether to proceed with conversion to open drainage or operation with decortication. This really depends on the radiographic appearance and the duration of the infection as well as the patient’s overall condition. Once the lung is “stuck,” which occurs fairly rapidly in the face of an intrapleural infection, the chest tube may be disconnected from water seal drainage, a gauze pad applied to the end of the now-open tube, and a radiograph obtained to assure that the lung has not “dropped.” If indeed the lung stays up, then the tube may be shortened and, as the authors point out, advanced over a period of time allowing the space to close over the tube. This can be a prolonged, uncomfortable process with the patient having to return for a number of outpatient visits. The open drainage tube needs to be in a dependent position. Open drainage may also be facilitated by an open window thoracostomy as long as the “window” is placed in a dependent location. This obviates the need for an uncomfortable tube sitting between ribs. If the open window is obstructed by the scapula, there is a tendency for it to close prematurely. If the optimal location for the window is near the scapula, we have resected a portion of the scapula to prevent it from interfering with the window. We also have not hesitated to go back and revise the window if it appears to be closing prematurely.

If the lung appears entrapped by a visceral pleural peel, then a decortication to allow for complete lung re-expansion is required. Whether one does this with a VATS approach or an open thoracotomy, the key is to completely remove the peel and to do this requires entering the appropriate plane between the peel and the visceral pleura. To do this most effectively, the peel has to be “mature,” that is, fibrous and not simply fibrinopurulent. Entering the decortication plane is not easy; I use a 15-scalpel blade with the lung expanded to provide counter traction. Care must be taken to go deep enough, but not too deep as to enter lung parenchyma. Using a combination of sharp and blunt dissection and maintaining a broad sweep, the peel is gradually removed. We trim off the peel as it is freed up so that we are not working in a deep hole under a “hood.” The areas of difficulty tend to be within the fissures. The lower lobe must be freed off the diaphragm as the authors point out. At times, the peel is so thin and so adherent that the only option is the “ham” the lung, which is creating cross hatching along the entire lung surface with cuts deep enough but not so deep that they enter the lung parenchyma. As in most things in life, in pleural infection timing is critical. The timing of initial drainage, the timing as to the duration of drainage, and the timing of further interventions, if needed.

LRK
Resection of Superior Sulcus Tumors
Christine Lau and G. Alexander Patterson

The term “superior sulcus” is really a misnomer in that there is no specific anatomic structure that corresponds but the term has come to refer to those primary lung tumors that occur in the apex of the lung that involve the chest wall and often other structures that reside in the thoracic outlet. These lesions can present with pain in the nerve distribution of the eighth cervical and first and second thoracic nerve roots. In addition, Horner syndrome may be present as a result of involvement of the stellate ganglion of the sympathetic chain. Such patients have the classic presentation described by Pancoast–Tobias syndrome. Patients with C8–T1 nerve root involvement may also present with typical neurologic findings of the “ulnar hand.” However, the majority of patients with apical lung tumors present with nondescript but persistent shoulder or upper chest pain. Many of these patients are seen by orthopedic surgeons or chiropractors and are treated as if the problem is strictly a tendonitis or other orthopedic problem, and the only imaging studies obtained are shoulder films that when viewed in retrospect clearly show the lesion. It is not uncommon for patients to be treated for many months prior to a correct diagnosis being made. Posterolateral chest radiographs may demonstrate nothing more than apical pleural thickening. Computed tomography (CT) and magnetic resonance imaging (MRI) usually depict the lesion clearly.

ANATOMIC CONSIDERATIONS
The insertion of the anterior, middle, and posterior scalene muscles on the first and second ribs, respectively, divides the thoracic inlet into three compartments (Fig. 32.1). The anterior compartment contains the platysma and sternocleidomastoid muscles, the external and anterior jugular veins, the inferior belly of the omohyoid muscle, the subclavian and internal jugular veins and their major branches, and the scalene fat pad. The middle compartment includes the anterior scalene muscle with the phrenic nerve lying on its anterior aspect, the subclavian artery with its primary branches except the posterior scapular artery, the trunks of the brachial plexus, and the middle scalene muscle. Finally, the posterior compartment, which lies posterior to the middle scalene muscle, includes the long thoracic and external branch of the spinal accessory nerves, the posterior scapular artery, the sympathetic chain and stellate ganglion, vertebral bodies, intervertebral foramina, and intercostal nerves.

CLINICAL CONSIDERATIONS
The anatomic location and the pattern of invasion of the apical lung lesion determine the presenting symptoms and signs. Anterior apical tumors generally present with chest wall or shoulder pain. Hand or arm swelling suggests subclavian vein invasion on the left or brachiocephalic invasion on the right. The phrenic nerve may be involved as it crosses the scalenus anticus muscle. These anterior lesions usually do not involve the brachial plexus.

Tumors invading the middle compartment of the thoracic inlet may present with signs and symptoms related to compression or infiltration of the middle and lower trunks of the brachial plexus, which manifest clinically as pain radiating to the shoulder and upper extremity. Often these tumors spread along the fibers of the middle scalene muscle.

Tumors located posteriorly are usually located in the costovertebral groove and commonly present with some or all the signs and symptoms of the Pancoast–Tobias syndrome, because of the involvement of the C8 and T1 nerve roots, the posterior aspect of the subclavian and vertebral arteries, the sympathetic chain, the stellate ganglion, and preganglionic muscles. These tumors have a propensity to spread along the nerve roots up to the spinal canal through the intervertebral foramina. In addition, vertebral bodies may be involved by direct extension.

DIAGNOSTIC CONSIDERATIONS
Unfortunately, the diagnosis of superior sulcus tumor is often made late because symptoms are not specific, neurologic findings are sometimes absent, and routine imaging of the chest and shoulder are often not revealing. Often symptoms are mistakenly attributed to arthritis or other inflammatory conditions of the shoulder or cervical spine. The radiologic findings can be subtle because these lesions are often hidden behind the first rib and clavicle. Posteroanterior and lateral chest X-ray have little role in evaluation of the superior sulcus tumor. Superb imaging of the lesion and its local extension can be obtained using modern computerized tomographic techniques. High-resolution images with three-dimensional volume averaging allow precise location of extent of the tumor, nerve involvement, and spinal invasion. Specific nerve root or vascular invasion is better assessed by MRI. The easiest way to obtain a tissue diagnosis is by fine-needle aspiration biopsy. Transbronchial biopsy may be considered, but these lesions are so peripheral that this option is rarely useful. If there is a suspicion of extensive pleural invasion or pleural metastases, video-assisted thoracic exploration may be utilized for diagnostic purposes. All patients should undergo a thorough search for hematogenous metastases. Positron emission tomography (PET) imaging should be a routine part of the evaluation to assess both regional lymph node involvement and distant metastatic disease. Because these are T3 lesions, we employ mediastinoscopy and supraclavicular lymph node biopsy in every patient. Patients with N2 or N3 nodal involvement are not candidates for resection. The initial investigation of the potentially operable patient also includes preoperative cardiopulmonary functional tests and other investigations required for any major pulmonary resection.
The insertion of the anterior scalenus muscle (ASM), middle scalenus muscle (MSM), and posterior scalenus muscle (PSM) on the first two ribs divides the thoracic inlet into anterior, middle, and posterior compartments. Cl indicates the first cervical vertebral body. SA, subclavian artery; SV, subclavian vein.

**INDICATIONS**

Determination of specific root involvement is important. T1 invasion may be evident only from pain and paresthesia in the medial aspect of the upper arm. C8 invasion will be associated with loss of strength in intrinsic muscles, lack of thumb opposition, and numbness in the fifth finger and medial half of the ring finger. These observations can be confirmed by electromyography, but clinical examination is usually sufficient. Phrenic nerve invasion is detected by elevation and immobility of the ipsilateral diaphragm. Vascular invasion is usually apparent by good-quality contrast CT scans, but additional information can be obtained by MRI. If vascular invasion is suspected, arteriography may be helpful, and Doppler ultrasound will demonstrate associated cerebrovascular artherosclerotic changes, which might affect the decision regarding operability. Radiologic determination of vascular and nerve root invasion is sometimes equivocal. Apposition of the tumor to major structures does not confirm invasion or preclude surgical exploration to determine resectability (Fig. 32.2). Spinal invasion or extradural extension is often evident on CT scans, but occasionally MRI is necessary to rule out subtle spinal involvement.

These investigations are not merely academic. Extent of disease and, therefore, likelihood of complete resection must be determined preoperatively. Loss of the T1 nerve root is inconsequential, but resection of T1 and C8 will leave a severely impaired “ulnar hand,” which the patient may not accept. Subclavian vein or arterial invasion is not a specific contraindication to resection. The vein can be resected without reconstruction. Arterial resection will require primary reconstruction or interposition grafting. Vascular invasion describes a T4 lesion and predicts a decreased long-term survival. Limited involvement of the vertebra such as a transverse process or partial vertebral body involvement is not a contraindication to resection. In fact, these resections can be conducted with local resection of the affected bone to obtain tumor-free margins. Patients with more extensive single or double vertebral involvement may be candidates for complete resection. Recent advances in techniques of vertebral resection and spinal stabilization make such resection feasible. Limited experience with such resections has been reported from a small number of experienced centers, and early results are encouraging.

Absolute contraindications to resection include N2 or N3 disease, extensive vascular invasion, brachial plexus involvement more extensive than C8 and T1, and multiple-level vertebral involvement with extension into the spinal canal.

After the 1924 and 1932 reports of Henry K. Pancoast describing the tumors of the thoracic apex, the entity was considered incurable until the report of Chardack and MacCallum in 1956 and the description of Shaw and Paulson in 1961. Radiation therapy given preoperatively over a 10- to 20-day period at a dose of 30 to 45 Gy had been the standard approach since the Shaw
and Paulson report. In recent years, demonstration of tumor response following induction chemoradiation gave rise to an interest in its application in patients with superior sulcus tumors. A multicenter cooperative group trial demonstrated that cisplatin and etoposide and 45 Gy of radiation improved the rate of complete resection, pathologic complete response, local recurrence, and intermediate-term survival compared with historical controls treated only with induction radiotherapy. For this reason and because of the success of combined-modality therapy in stage IIIA lung cancer, induction chemoradiation has become the standard of care for superior sulcus tumors in most centers. It has also been pointed out by some authors that induction therapy should include higher doses of radiation as it has been shown that this does not increase perioperative morbidity but may result in a higher rate of complete response and ultimately long-term survival.

**PERIOPERATIVE PATIENT MANAGEMENT**

Preoperative preparation is as for any major pulmonary resection. A double-lumen endotracheal tube or bronchial blocking catheter for left-sided lesions is helpful. Standard monitoring lines include an arterial line in the contralateral radial artery. Two venous lines should be placed to allow for rapid volume replacement as needed.

**SURGICAL TECHNIQUE**

Different operative approaches are necessary depending upon the location of the primary tumor. The surgeon must be familiar with these various approaches. The goal of the operation is en bloc resection of the upper lobe along with involved ribs and other structures, including transverse processes, the lower roots of the brachial plexus, the stellate ganglion, and the upper dorsal sympathetic chain.

There are three approaches most commonly employed for these lesions. The posterior approach described by Shaw and Paulson is ideal for lesions situated posteriorly. The anterior cervicothoracic approach described by Dartevelle is ideal for the management of anterior lesions. The hemiclamshell approach is less commonly employed but is useful for anterior or posterior lesions.

We believe that whatever approach is selected, an initial cervical exploration is warranted. This is particularly true when a posterolateral Shaw–Paulson resection is anticipated. With the patient supine, shoulders elevated, neck extended, and head turned to the contralateral side, a transverse incision is made immediately above the clavicle. The platysma muscle is divided, as is the clavicular head of the sternomastoid muscle. The supraclavicular fat pad is excised and submitted for frozen-section examination to rule out the involvement of supraclavicular lymph nodes. The phrenic nerve is elevated away from the scalenus anticus muscle, so that the muscle may be divided. This exposes the subclavian artery and the lower roots of the brachial plexus. Anterior displacement of the brachial plexus exposes the scalenus medius muscle, which is then divided, taking care to preserve the long thoracic nerve. By mobilizing and inspecting these structures through a small cervical incision, tumor extent can be assessed and a judgment made regarding the possibility of subsequent complete resection before exposing the patient to the morbidity of a major posterior thoracotomy and rib resection. In addition, this anterior superior mobilization facilitates subsequent dissection and resection through the posterolateral thoracotomy.

**Posterolateral Approach (Shaw–Paulson)**

The patient is placed in the lateral decubitus position, leaning slightly forward. The upper arm is loosely supported by folded sheets and is free to move as the scapula is elevated. The skin preparation is carried out from the base of the skull (included are the spinal processes above C7) and down to the iliac crest and to the midline posteriorly and anteriorly.

**Incision**

A limited posterolateral incision is made, dividing the latissimus muscle, and entry is made into the chest through the fourth or fifth interspace. The pleural space and hilum are examined to exclude the presence of metastatic disease. This initial exploration also permits assessment regarding anterior (several centimeters away from the lesion) and inferior (one rib and one interspace) margins of resection.

Subsequently, the incision is extended superiorly between the spinous processes and the medial border of the scapula to the level of the seventh cervical vertebra (Fig. 32.3). The trapezius muscle is divided along the full length of the incision. The rhomboid muscles from superior to inferior are then divided in the line of the incision. The rhomboid muscles insert into the medial border of the scapula. Care should be taken to avoid injury to the dorsal scapular nerve and the satellite scapular artery, which run down the medial border of the scapula. The division of the rhomboid muscles elevates the medial border of the scapula from the chest wall.

A large Finocchietto retractor is then placed with its lower blade in the interspace incision and the upper blade on the tip of the scapula. Opening the retractor elevates the scapula off the chest wall and exposes the subscapular musculature. These muscles are then divided with cautery up to the level of the first rib.

**Chest Wall Resection**

The chest wall resection is completed first, allowing the lung to be completely mobilized and permitting a safer subsequent pulmonary resection. All involved chest wall should be resected en bloc. Extrapeural dissection without rib excision, mentioned only to be condemned, results in incomplete resection and almost certain local recurrence. The lowermost rib to be preserved is identified, and an interspace incision is made along its superior border, extending from the anterior margin of resection to the transverse process posteriorly. The division of the ribs is started anteriorly. Intercostal muscles are divided with electrocautery.

Using rib shears, the ribs are divided anteriorly in succession from inferior to superior (Fig. 32.4). Traction on the previously divided anterior margins of the involved ribs exposes the anterior aspect of the first rib. For posterior tumors, the anterior aspect of the first rib can easily be encircled and divided with angled rib shears. The anterior and middle scalene muscles, previously divided from above, are exposed. The posterior scalene muscle is
Chapter 32: Resection of Superior Sulcus Tumors

Fig. 32.4. Using rib shears, the ribs are divided anteriorly in succession from inferior to superior after the neurovascular bundle is ligated or clipped. (Adapted from Urschel HC, Cooper JD, eds. Atlas of Thoracic Surgery. New York: Churchill Livingstone; 1995:185, Fig. D.)

Fig. 32.5. The rib may be disarticulated from the transverse process in the costotransverse angle if the parietal pleura and not the ribs or vertebrae are invaded by the tumor.

Fig. 32.6. The osteotomy is performed at the level of the transverse process if the tumor erodes the rib posteriorly.

Fig. 32.7. If the tumor is fixed to the paravertebral fascia, a partial excision of the vertebral body can be done as illustrated here.

divided where it crosses the lateral border of the first rib. The superior margin of the first rib is then exposed by careful superior mobilization of the subclavian vein, artery, and inferior aspect of the brachial plexus. At this point, the operation is continued posteriorly.

The erector spinae muscle is incised along its anterior border and retracted posteriorly from the first rib to the lowermost resected rib. This exposes the angle of the invaded ribs and transverse processes. Hemostasis can be obtained by packing the space between muscles and bony structures. If there is no radiologic evidence of rib or spinal invasion, the transverse processes can be left intact. The costotransverse process joint is opened, and the heads of the ribs are disarticulated by placing a periosteal elevator in the joint and levering forward (Fig. 32.5). This elevates the head of the rib from the spine. If rib invasion is present, leaving the transverse processes compromises the margin of resection. Therefore, the transverse processes (Fig. 32.6) and (if rib heads are involved) lateral cortex of the vertebra are amputated using an osteotome (Fig. 32.7). With completion of the bony resection at each level, the intercostal bundle is ligated and divided with the intercostal nerve ligated at the level of the neural foramen. Occasionally, significant venous hemorrhage is encountered from the orifice of the intervertebral foramen. Loose packing with hemostatic material can be used, taking care to avoid excessive pressure, which can result in migration of material into the spinal canal or occlusion of the anterior spinal artery. This posterior portion of the resection is continued superiorly until the angle of the first rib is reached.

Dissection of the Brachial Plexus
At this point, the first thoracic nerve (T1) below and the eighth cervical nerve (C8) above the neck of the first rib are visualized. The head of the first rib is then disarticulated from the spine. Usually, the T1 nerve is involved as it crosses the first rib. The nerve root is ligated or clipped and divided as it emerges from the intervertebral foramen. If the eighth cervical nerve is not involved, every effort should be made to protect it (Fig. 32.8). If the tumor also involves the eighth cervical nerve, the nerve...
Section I: General Thoracic Surgery

root can be divided at the intervertebral foramen and the lower trunk of the brachial plexus divided lateral to the area of invasion. The nerve roots are ligated or clipped to prevent cerebrospinal fluid (CSF) leak. If a CSF leak is noted, the foramen should be covered with a pedicled flap of erector spinae muscle in an effort to help seal the leak.

Dissection of Subclavian Vessels
Dissection of the subclavian artery can usually be carried out in a subadventitial plane (Fig. 32.9). Branches such as the internal mammary artery and the thyrocervical trunk are ligated and transected as necessary. If the subclavian artery is invaded, it should be cross-clamped (after adequate systemic heparinization, e.g., 0.5 mg/kg) proximal and distal to the involved segment and reconstructed either by an end-to-end anastomosis or by interposing a polytetrafluoroethylene graft (6 or 8 mm). If the subclavian vein is involved or occluded by tumor, the segment of vein should be excised and the proximal and distal ends suture ligated. No attempt should be made to bypass the excised segment of vein. Management of the subclavian vessels can be difficult through the posterior approach, particularly if the tumor extends medially. In this circumstance, it is sometimes necessary to resect a segment of the anterior scalene muscle and phrenic nerve.

Vertebral Body Resection
Limited invasion of the body of the vertebra mandates vertebrectomy for complete resection. Recent advances in spinal instrumentation allow complete resection of tumors involving vertebral bodies or neural foramina (Fig. 32.10). This is a reasonable strategy for limited vertebral invasion (one or two vertebral bodies) without extension into the spinal canal. For more extensive spinal invasion, there is no justification for resection.

For en bloc resection of the involved vertebrae with the chest wall and lobe, a transcervical as well as a posterior midline approach is used, or alternatively a cervicothoracic transmanubrial approach plus a midline posterior incision can be used. The anterior incision is used to assess resectability. Tumor-bearing structures are removed with lateral division of the involved nerve roots, ribs, and partial midline division of the vertebrae. A standard lobectomy is performed leaving the lobe in place. After this, the posterior midline approach is used for unilateral laminectomies, nerve root division within the spinal canal, and midline vertebral body division. After the resection is complete, spinal stabilization is performed.

Pulmonary Resection
The chest wall specimen is still attached to the upper lobe. Anatomic upper lobectomy is the preferred parenchymal resection even if the lesion is small. The lobectomy is performed through the defect created by the chest wall resection or through the original exploratory intercostal incision (Fig. 32.11). Complete mediastinal node dissection or, at the minimum, nodal sampling is mandatory.

Postresection chest drainage is accomplished through two separate chest tubes, one of which must be placed at the apex of the pleural space. For chest wall resections down to the fourth rib, the scapula covers the chest wall defect, and therefore prosthetic reconstruction is not necessary. Muscle, subcutaneous tissue, and skin closures are accomplished in a standard manner.

Tatsamura proposed an approach for apical lung tumors that invade the thoracic inlet in which an incision is started at the level of the spinous process of the second or third thoracic vertebra,
continued downward along the paravertebral line around the tip of the scapula, and
continued upward to above the nipple level, following the axillary line up to the level
of the sternoclavicular joint (Fig. 32.12). The management of the thoracic inlet
through this incision is the same as for the Shaw–Paulson and anterior approaches.

Anterior Approaches

Transclavicular Approach

This approach is ideally suited for anterior lesions. The patient is placed in the supine
position with the shoulders elevated, the neck hyperextended, and the head turned
away from the involved side. The operative field extends from the mastoid down to the
xiphoid process and from the midaxillary line laterally to the hemiclavicular line.

An L-shaped incision is made that includes an oblique presternocleidomastoид incision extended horizontally below the clavicle and lateral to the deltopectoral
groove (Fig. 32.13). By raising a sub platysmal flap laterally, one can resect the
supraclavicular fat pad and rule out supraclavicular N3 disease. The sternoclavicular muscle is freed up inferiorly from the clavicle and manubrium to create a myocutaneous flap, which is then reflected back
to yield a full exposure of the neck and the

thoracic inlet. Superior mediastinal invasion is assessed by inserting a finger along the lateral aspect of the tracheoesophageal groove. Extension of the tumor into the thoracic inlet is carefully assessed. Resection through this approach requires visualization of the thoracic inlet immediately posterior to the medial clavicle. Dartevelle and colleagues described resection of the medial clavicle. However, medial clavicular resection can result in significant morbidity and limitation of shoulder motion postoperatively. A number of authors have described techniques that preserve the sternoclavicular joint and elevate the entire clavicle from medial to lateral. After resection is complete, the clavicle–sternal unit is rigidly fixed back to the sternum.

Dissection of the Subclavian Vein

Division of the internal, external, and anterior jugular veins makes visualization of the venous confluence at the origin of the innominate vein easier. On the left side, the thoracic duct should be identified, ligated, and divided. Division of the internal jugular vein improves exposure of the subclavian vein. If the subclavian vein is involved, it should be resected after proximal control and distal control have been achieved. The phrenic nerve is evaluated and preserved whenever possible. The anterior scalene

![Fig. 32.13](image3.png)

Fig. 32.13. Right transcervical incision. The patient is placed in the supine position with the neck hyperextended and the head turned away from the involved side. An L-shaped skin incision is made from the angle of the mandible down to the sternal notch. This is extended horizontally under the internal half of the clavicle and prolonged into the deltopectoral groove or into the bed of the second/third intercostal space, as indicated by the extension of the lesion.
muscle is then divided either at its insertion on the scalene tubercle of the first rib or well away from the tumor (Fig. 32.14). If the tumor has invaded the superior aspect of this muscle, the muscle should be divided at the insertion on the anterior tubercle of the transverse processes of C3 through C6.

Dissection of the Subclavian Artery
As for the posterior approach, the subclavian artery is mobilized by dividing branches as necessary. The vertebral artery is sacrificed only if involved and provided that no significant extracranial occlusive disease was detected on preoperative Doppler ultrasound examination. Usually, the artery can be dissected away from the tumor. If invaded, the artery should be resected and reconstructed as described for the posterior approach (Fig. 32.15).

Dissection of Brachial Plexus
The middle scalene muscle is divided above its insertion on the first rib or higher as indicated by the extension of the tumor. Depending on the extent of the tumor, especially if there is invasion of the middle compartment of the thoracic inlet, the muscle may have to be taken by dividing the attachments to the posterior tubercles of the transverse processes of the second through seventh cervical vertebrae. The nerve roots of C8 and T1 are then easily identified and dissected distally until they coalesce to form the lower trunk of the brachial plexus. Thereafter, the prevertebral muscles are detached along with the dorsal sympathetic chain and stellate ganglion from the anterior surface of the vertebral bodies of C7 and T1. This permits visualization of the intervertebral foramina. The T1 nerve root, if involved, is divided proximal to the tumor at the level of the intervertebral foramen. Although the tumor may extend well superior into the brachial plexus, neurolysis is usually achieved without division of any nerve roots above T1. Damage to the lateral and long thoracic nerves should be avoided to prevent a winged scapula.

Chest Wall Resection
The chest wall is divided anteriorly. For true anterior lesions, this may require resection of the lateral border of the sternum down to the lowest rib of resection. For lesions more lateral in location, the costal cartilage can be divided from the sternum. The intercostal space is divided laterally and posteriorly well beyond the margins of tumor involvement. The resected ribs
are then divided or disarticulated from the spine through tumor-free margins.

Pulmonary Resection
An anatomic upper lobe en bloc resection can be performed through the chest wall defect. The anterior superior exposure mandates resection from anterior to posterior, that is, on the right division of the superior vein, arterial branches, and bronchi; on the left, superior vein, upper lobe bronchus, and arterial branches. It is rarely necessary to reposition the patient after closure of the anterior wound and complete the lobectomy through a standard postero-lateral thoracotomy. However, it is very difficult, if not impossible, to visualize the inferior pulmonary ligament and divide it safely through this anterior superior defect without videothoracoscopic equipment.

Chest Wall Closure
If the medial clavicle is resected, the sternomastoid muscle is fixed to the upper edge of the sternum. An anterior skeletal chest wall prosthesis is advised if the second rib and mandatory if the third rib is included in the resection. Marlex methylmethacrylate, Gore-Tex, and Prolene mesh are useful substitutes. Standard closure and chest drainage is employed.

Hemiclamshell or Trap-Door Incision
The hemiclamshell or trap-door incision combines a partial sternotomy and anterior thoracotomy (Fig. 32.16). The patient is positioned supine, usually with the ipsilateral upper division and one of the involved ribs are then performed. The incision is then extended superiorly through the upper sternum extending along the anterior border of the sternomastoid muscle. The internal mammary arteries are ligated and divided. A retractor or sternal hook is then placed, elevating the chest wall superolaterally. This allows exposure of the upper half of the superior mediastinum and the apex of the thoracic cavity. The superior vena cava and ipsilateral innominate vein are then dissected laterally until the clavicle is removed for better exposure of the subclavian vessels and brachial plexus. The involved ribs are divided at the costochondral or costosternal junctions, and the appropriate intercostal space is entered below visible tumor. The posterolateral aspects of the involved ribs are then divided, and the specimen is released within the chest cavity superiorly, remaining attached to the apical fascia. The dissection and management of the subclavian vein, artery, and brachial plexus are similar to those described for the transclavicular approach, and a lobectomy is completed.

Masaoka Incision
The Masaoka incision involves an upper median sternotomy combined with an incision in the anterior fourth intercostal space below and a transverse cervical incision at the base of the neck superiorly (Fig. 32.17). Dissection then proceeds as described.

CONCLUSIONS
Tumors of the pulmonary apex are challenging lesions to treat because of their close association and often involvement of surrounding structures within the thoracic inlet (brachial plexus, subclavian vessels, or spine). A multimodality approach consisting of induction chemoradiation followed by resection is the standard for patients deemed preoperatively to have resectable disease. As for any lung cancer resection, negative resection margins should always be the intent as this has been shown to be associated with significantly improved survival. The choice of incision is important. Anterior approaches have allowed complete resections of anterior apical lesions involving the subclavian vessels. Newer techniques of spine resection and stabilization enable

SURGICAL COMPLICATIONS AND POSTOPERATIVE CARE
The potential complications that may occur after resection of apical lung tumors are similar to those for any major pulmonary resection. There are several complications unique to these resections. A CSF leak, if noted intraoperatively, must be sealed. This may require neurosurgical consultation, foraminotomy, and direct dural repair. If identified postoperatively by clear fluid drainage from chest tubes, aggressive management including re-exploration should be undertaken. Consequences of a persistent CSF leak such as subarachnoid or ventricular air embolism and meningitis warrant aggressive management.

The possibility of Horner syndrome and nerve deficits secondary to division of nerve roots should be discussed with the patient preoperatively. Resection of the lower trunk of the brachial plexus (C8 and T1) results in an atrophic paralysis of the forearm and intrinsic muscles of the hand (Klumpke–Déjerine syndrome). This can be a disabling situation for the patient. Hemotherax may occur as a result of chest wall resection along with the difficulty and risks of securing small veins at the level of the intervertebral foramina. Chylothorax is also a possible complication and can be avoided by individual ligation of the thoracic duct and its branches. If chylothorax is identified and persists, aggressive management including thoracic duct ligation is mandatory. If the subclavian vein has been resected, the ipsilateral forearm should be elevated to facilitate venous drainage and minimize edema. The radial pulse must be monitored to assess the patency of the revascularized subclavian artery.
complete resection in patients with posterior tumors with vertebral involvement.

**SUGGESTED READINGS**

Despite the title of the chapter there does not exist, in my opinion, a superior pulmonary sulcus or at least I have never been able to identify this as an anatomic structure. The term has persisted. Perhaps it would be better to label these as “apical lung tumors” and recognize that not all apical lung tumors are so-called Pancoast tumors. The important distinction involves the recognition of those apical lung tumors that involve structures in the thoracic inlet so that preoperative chemoradiotherapy can be given, because this regimen has been shown in a large intergroup trial to be associated with improved survival when compared with historical controls. This preoperative regimen has now become the standard of care for these lesions, supplanting the time-honored, but poorly tested, radiation therapy alone given in 30-Gy fractions over a 10-day period. Preoperative radiation therapy had been given for these lesions since the initial description by Shaw and Paulson despite a lack of data demonstrating efficacy.

Establishing the diagnosis of an apical lung tumor can be difficult, and patients often have been followed for many months with shoulder pain attributed to musculoskeletal problems before a chest radiograph and chest CT scan are obtained. The apex of the lung is a difficult area to interpret on the chest radiograph, and this area accounts for a large percentage of lesions missed by radiologists. Persistent shoulder pain in a smoker without a specific inciting cause should be looked at with great suspicion and ideally a chest radiograph and CT scan should be obtained early following presentation of such a patient. Apical lung lesions are the one area where MRI scans, and especially the coronal reconstructions, have added to our diagnostic capabilities and enhanced our operative planning expertise. MRI provides a significant improvement in our ability to visualize the brachial plexus as well as the brachiocephalic vessels and allows for a determination as to the probability of invasion of these structures.

A needle biopsy, either an aspiration or a core biopsy, should be performed to establish a histologic diagnosis and I agree with the authors’ recommendation of sampling the supraclavicular fat pad prior to proceeding with resection, even when this area is not clinically suspicious. PET scanning may point to this area, but because of the close proximity with the primary tumor, it may not be possible to distinguish nodal disease from the primary tumor. My preference is to perform a bronchoscopy and mediastinoscopy with supraclavicular fat pad biopsy as a separate procedure before initiating preoperative chemoradiotherapy, because if N2 or N3 disease is present the patient is not a candidate for resection and the “curative” radiation therapy course will differ from that given as a preoperative regimen.

As opposed to the authors, it is my feeling that the anterior cervicothoracic approach through an L-shaped incision along the anterior border of the sternoclavicularis is the preferred approach for all apical lung tumors including posterior ones. One should keep in mind that the distance between anterior and posterior at the thoracic inlet is only a few centimeters. The anterior approach offers significantly improved access to the brachiocephalic vessels and the brachial plexus and still allows for complete chest wall excision and potentially vertebral body resection. Either the medial portion of the clavicle may be excised or, as we prefer, division of the manubrium and anterior portion of the first rib with elevation of the intact sternoclavicular joint and hemimanubrium. As opposed to the posterior approach, where the rib is disarticulated from the transverse process and then levered off the vertebral body, from the anterior approach the head of the rib is taken first and the neck subsequently separated away from the transverse process. We reserve the hemiclamshell incision for very large upper lobe lesions involving the thoracic inlet, feeling that the cervicothoracic approach works well in essentially all cases. The anatomic pulmonary resection can always be accomplished through the anterior incision, and we have never found it necessary to reposition the patient for a posterostral thoracotomy in order to carry out the lobectomy. Again it should be emphasized that an anatomic lobectomy is the required parenchymal resection even though it might be tempting to simply do a wedge excision since only a very peripheral portion of lung parenchyma is usually involved. This temptation to try to get away with less than an anatomic lobectomy should be avoided.

(continued)
With respect to some of the smaller technical details, we use bipolar cautery if bleeding is encountered at the level of the neural foramen and avoid any packing with hemostatic material. CSF leaks should be assiduously avoided by careful ligation of the neurovascular bundle prior to division. If a leak is detected, it is insufficient to simply pack the area and a neurosurgery colleague should be consulted, to directly repair the dural rent by exposing the dural tear via a foraminotomy. It is optimal to recognize a CSF leak at the time of the initial operation but if a CSF leak is recognized postoperatively, a skull film should be obtained to see whether air is present in the ventricles. It may be necessary to send fluid for a glucose assay to verify that indeed the chest drainage is CSF. With a CSF leak, the patient will usually have a headache. Once a leak is demonstrated, a neurosurgeon should be involved. Conservative management involves placing a spinal drain, but as the authors point out, optimal treatment involves taking the patient back to the operating room for a direct dural repair. A CSF leak that is not dealt with aggressively exposes the patient to the risk of meningitis, something that should clearly be avoided.

A potential pitfall for the surgeon inexperienced in working around the spine and especially at the level of C8 and T1 is not carrying the dissection back to the level of the vertebral foramina where both nerve roots may be seen originating and subsequently forming the lower cord of the brachial plexus. If the dissection is not carried back to that level, it is possible to divide the lower cord of the brachial plexus mistaking it for the T1 nerve root. The head of the first rib sits between the C8 and T1 nerve root and is the key anatomic landmark for identifying these structures. Dividing the lower cord of the brachial plexus leaves the patient with a useless hand as the loss of the intrinsic muscle function results in a clawed hand.

LRK
INTRODUCTION
Thoracic sympathectomy has undergone significant change since its initial description over 100 years ago. Originally described utilizing a posterior approach, the procedure has changed over the years from a supraclavicular approach and transaxillary thoracotomy to multiport thoracoscopy and, most recently, single-port thoracoscopy. Indications for a thoracic sympathectomy include the treatment of reflex sympathetic dystrophy (RSD), Raynaud’s Disease, chronic pancreatic pain, and, most commonly, hyperhidrosis. Hyperhidrosis presents as severe sweating of the face, hands, axillary regions, feet, or any combination of these and is present in at approximately 2% of the population.

ANATOMY
The thoracic sympathetic chain exists as a paired group of, up to, 12 interconnected ganglia that correspond to each thoracic nerve. The chains lie in either pleural space on the ventral surface of the ribs just lateral to the costo transverse process articulation (Figs. 33.1 and 33.2). The sympathetic chains take a more lateral position as they travel more inferiorly in the chest. Each ganglion lies below the corresponding rib where division of the sympathetic chain occurs. Thus, an R3 sympathectomy would be defined as the division of the sympathetic chain over the third rib.

Nonsurgical Management
Nonsurgical management of primary hyperhidrosis includes the use of oral and topical agents, the application of botulinum toxin (Botox), and the use of electrical currents known as iontophoresis. Oral agents used are anticholinergic drugs and include glycopyrrolate, oxybutynin, and propantheline. These drugs work by muscarinic receptor blockade but have the disadvantage that their action is not specific to the areas of increased sweating. Common side effects include dry mouth and eyes, blurred vision, and urinary retention.

Iontophoresis involves the use of an electrical current that flows through a water bath where hands or feet are placed. Clinical success rates can be as high as 80%, and the treatment effects can last anywhere from 2 months to a year. Side effects of iontophoresis are mild and usually well tolerated. Topical agents usually involve an aluminum-based chemical ointment or cream, which can be applied to hands, feet, or axillary regions. Results of topical agents are variable and
side effects are usually related to local skin reactions. Botulinum toxin injections for palmar, axillary, and pedal hyperhidrosis have also been used with good success rates but this treatment is not always well tolerated by patients and requires repeated injections over time.

**SURGICAL MANAGEMENT**

Surgical management has evolved from transaxillary and supraclavicular incisions to small incision single-port thoracoscopy. Recent controversy has focused on which levels to perform the sympathicotomy, how many levels to treat, and whether to divide or clip the sympathetic nerve. The ideal site of nerve division takes into consideration trying to achieve the best results with the lowest incidence of side effects, primarily compensatory sweating (CH). Although several different opinions exist, the recent consensus includes division of the sympathetic chain over the third rib (R3) for palmar hyperhidrosis and R3, R4 or R4, R5 for palmar–axillary or axillary hyperhidrosis. Facial blushing can be treated by an R2 division above the level of the second rib but care must be taken to avoid injury to the stellate ganglion.

Although most surgeons choose to divide the sympathetic nerve with electrocautery, clipping of the nerve has also been described. The primary reason given for sympathetic nerve clipping is to allow for clip removal and sympathicotomy reversal in the case of poor results or undesirable side effects. However, this
reversal has been found to be inconsistent and must take place within the first 2 weeks of the procedure to have a good chance at working. Other techniques such as thoracoscopic sympathetic block have been described. This technique utilizes injection of a local anesthetic into the sympathetic chain to create a temporary sympathetic block to replicate the effects of a sympathectomy.

**Surgical Technique**

Thoracoscopic sympathectomy is performed under general anesthesia utilizing a single-lumen tube. Patients are placed in a supine position with their arms abducted to 90 degrees and care is taken to avoid injury to the brachial plexus. The chest and both axillae are prepped into the surgical field but there is usually no need to remove any axillary hair for the procedure. An area at the edge of the axillary hairline is then injected with a local anesthetic and a 5-mm incision is then made in this area with a No. 15-blade scalpel. Next, ventilation is held and a mosquito clamp is used to dissect into the pleural space over the top of the fourth rib. A 30-degree 3-mm thoracoscope is then placed into the pleural space and ventilation is resumed. A Veress needle (Ethicon, Inc., Somerville, NJ) is then placed alongside the thoracoscope, and the pleural space is insufflated to 10 mmHg with CO₂. The sympathetic chain is then identified and usually the CO₂ can be stopped. Visualization at this point is also added by decreasing the tidal volume used to ventilate the patient. Once the desired level of sympathectomy and all accessory nerves are identified, a 2-mm electrocautery is placed through the incision, next to the scope, and the sympathetic nerve is divided over the desired rib. The transected ends of the nerve are then separated by 1 to 1.5 cm to prevent regrowth (Fig. 33.5). All accessory nerves overlying the target ribs are then divided in the same manner. The electrocautery is then removed and replaced with a 2 or 3 mm suction, which is used to evacuate all air and CO₂ from the pleural space. The incision can be closed with a single absorbable stitch and the same procedure is performed on the contralateral side. An alternative approach is to use two thoracoscopic sites and a slightly larger scope (5 mm) until the surgeon is familiar with the anatomy and the technique. The patient is then extubated and taken to the recovery unit where a chest radiograph is performed. Results are usually realized immediately after surgery. Patients should be able to be discharged from the hospital the day of the procedure.

The presence of an azygous lobe on the right can make the procedure a little more difficult. This situation can be dealt with by making one more 5-mm incision, on the right, and placing a 3-mm grasper through the incision to retract the azygous lobe away from the sympathetic nerve. Adhesions encountered primarily or secondary to previous surgery can be dealt with in a similar manner. The additional grasper can be used to retract the lung while the 2-mm cautery is used to divide the adhesions. Care should be taken to avoid injury to some of the larger intercostal veins, which can be difficult to control with the small cautery.

**Results, Complications, and Side Effects**

Results for palmar and axillary hyperhidrosis tend to be good with over 85% of patients expressing satisfaction with their outcomes. In the author’s own series, sympathectomy was successful in 99% of patients undergoing operation for palmar hyperhidrosis. Results tend to be slightly better for patients undergoing surgery for palmar or palmar–plantar hyperhidrosis than for axillary or palmar–axillary hyperhidrosis. Patients who undergo operation for facial blushing, on the other hand, only report excellent results in only 30% to 60% of cases.

The most common complication of thoracoscopic sympathectomy is postoperative pain that can present as discrete pain at the thoracoscopic sites or as a band-like tightness, which can be troubling to patients if they are not forewarned. Pain is usually treated effectively with oral analgesics and anti-inflammatory drugs. Intravenous ketorolac can be used intraoperatively in patients who do not have contraindications to nonsteroidal anti-inflammatory drugs, to help minimize postoperative pain. Chronic postoperative pain syndromes are rare and occur in <1% of all patients. Nerve injury can occur and most commonly involves injury of the intercostal brachial nerve at the site of the thoracoscopy incision. This can lead to numbness on the lateral aspect of the breast and medial aspect of the biceps area and is usually self-limited. Injury to the brachial plexus has been reported and is usually due to excessive abduction of the arms. Care should be taken during position of the patient to only abduct the arms enough to provide adequate exposure to the axillae.

Pneumothorax has been reported in up to 5% of patients after thoracoscopic sympathectomy. This can be due to failure to evacuate all CO₂ from the pleural space or from lung injury. Most patients can still be discharged on the day of the procedure as long as chest radiography demonstrates that the pneumothorax is not expanding and the patient is asymptomatic. Rarely, a persistent air leak is identified intraoperatively. This is more common in reoperations or in patients who require a pneumolysis for adhesions. A small pleural drain can be placed through the thoracoscopy incision and often removed several hours later, or the following day, once the air leak has resolved.

Bleeding complications occur in <5% of patients and can be due to injury to an intercostal vessel, superior vena cava, subclavian artery, or aorta. Care should be taken to ensure that the thoracoscopy incision is made at the third intercostal space and that dissection is performed over the fourth rib. Venous branches may be found coursing over the sympathetic chain. Small veins can be divided easily with electrocautery but larger veins should be avoided since injury to this structures can be difficult to control with cautery alone. If a larger vein is found to be obscuring the sympathetic nerve, the site of sympathectomy can be moved slightly cephalad or caudal to avoid vein injury.

Horner’s syndrome, which includes ptosis, miosis, and anhidrosis on the affected side, is due to injury of the stellate ganglion, which is located just below the first rib. Most occurrences of Horner’s syndrome are transient and are likely due to edema caused by manipulation during the sympathectomy. Permanent Horner’s syndrome has been reported in as many as 5% of patients, but the acceptable incidence should be <1%. Aberrant location of the stellate ganglion may, rarely, be a cause for injury but, more commonly, injury is...
due to incorrect site of sympathicotom y due to an error in rib counting. Care should be taken to identify the proper anatomic landmarks and if uncertainty still exists then the sympathicotom y can be moved slightly caud al.

Cardiac arrhythmias can occur but are rare, occurring in fewer than 1% of patients undergoing surgery for hyperhidrosis. The presumed mechanism is stimulation or disruption of the cardiac pacemaker's fibers that are supplied by the lower cervical and upper thoracic sympathetic ganglia. Bradycardia, tachycardia, intraoperative cardiac arrest, and ST and QT segment changes have all been reported. Symphaticotomies limited to R3 or R3/R4 may only disrupt a small portion of the nerve fibers innervating the heart and therefore permanent dysrhythmias should be rare.

The most common side effect of thoracic sympathicotom y is compensatory hyperhidrosis. CH can occur in up to 30% of patients following operation for hyperhidrosis and is defined as an increase in sweating in the trunk, groin, and thigh areas. CH can be mild-to-severe and usually is the reason for lower satisfaction rates. The mechanism of CH is felt to be due to either compensatory changes created by disrupting sweat gland function in the target areas or changes with hypothalamic feedback; however, the exact cause remains unknown. Several risk factors have been associated with an increased risk for CH and include the level of sympathicotom y, number of levels divided, obesity, and the presence of significant preoperative sweating in the trunk, thigh, and groin areas. Currently, there is no optimal treatment for CH but options include the same modalities used for nonsurgical treatment of hyperhidrosis. Patients should be counseled extensively about the risk of CH and in patients at significant risk for CH, thoracoscopic sympathectom y, prior to sympathicotom y, may be a reasonable first step to assess the severity of compensatory sweating.

Gustatory sweating and phantom sweating can occur in up to 40% of patients. Gustatory sweating manifests as facial sweating that occurs while eating and its pathophysiology is poorly understood. Phantom sweating presents as a sensation that a patient is, or is about to start, sweating in the target areas. It is usually self-limited and is best treated by making patients aware of the phenomenon preoperatively.

Recurrent sweating can occur in up to 10% of patients, years after their operation, depending on specific target area. Plantar hyperhidrosis has the highest recurrence rates and can be seen within a year after surgery. Reoperation with division of accessory nerves or sympathicotom y one or two levels below the original sympathicotom y or sympathectom y has been reported with good results. The risk of recurrent sweating should be discussed with patients as part of their preoperative counseling.

OTHER INDICATIONS FOR SYMPATHICOTOMY

Division of the sympathetic chain can also be used to treat R ynaud's syndrome, RSD, chronic pancreatic pain, and cardiac abnormalities such as long QT syndrome or certain tachycardia syndromes. There is a paucity of literature reporting results for these diseases and results tend to be less successful than those reported for hyperhidrosis. That being said, early pain reduction in patients with severe pain due to chronic pancreatitis can be high as 80% with a bilateral sympathicotom y from R4 to R10. This procedure usually requires the use of a double-lumen endobronchial tube and is facilitated by placing the patient in the lateral decubitus position.

CONCLUSION

The popularity of thoracic sympathicotom y has grown in the last decade as advances in technology have allowed for smaller, single-port, thoracoscopic access and as our understanding of results, complications, and side-effects has increased. The majority of patients report excellent results with thoracoscopic sympathicotom y for palmar, palmar–plantar, and axillary hyperhidrosis. Nevertheless, patients still report problems with recurrences and severe compensatory hyperhidrosis. This later problem, in particular, can be worse to a patient than their original hyperhidrosis. Problems with severe CH are compounded by the fact that currently there is no optimal treatment for this phenomenon. Planning for thoracic sympathicotom y should involve a detailed discussion with the patient about the expected results, complications, and possible side effects.

SUGGESTED READINGS

The advent of thoracoscopic sympathectomy, more properly known as sympathicotom as Dr. Force points out, has focused attention on the previously unrecognized significant incidence of hyperhidrosis that exists within the population. The procedure has evolved from one where a double-lumen endobronchial tube was placed and three incisions were made to one that may be performed with a 2-mm thoracoscope and a 2-mm electrocautery. In addition, there have been significant modifications made in the number of levels where the sympathetic chain is divided as well as a recognition that a ganglion does not need to be resected. Some surgeons have further modified the procedure by choosing to simply place a clip on the sympathetic chain avoiding division of the chain. Measuring digital skin temperature during the sympathicotom y may be used to assess the efficacy of the procedure. A rise in digital temperature should occur soon after the sympathetic chain is either clipped or divided.

When we first began doing this procedure for palmar hyperhidrosis, we were impressed with immediate relief patients received and how incredibly pleased most of them were, having suffered for years with the embarrassment that came every time they would go to shake someone’s hand. In addition, patients were even more pleased when their plantar sweating was significantly diminished as well. We recognized early on that for axillary hyperhidrosis and even more for facial sweating that overall results were not as favorable. Thus, patient selection is critical to obtain the best results. What we did not anticipate was the very high incidence of compensatory hyperhidrosis (CH) that occurs. In fact, I would go so far as to say that it is the rare patient who does not have CH. That is how commonly it is seen. Fortunately, most patients experience relatively minor CH and clearly express that it is far preferable to palmar or axillary sweating. But there is a significant and real incidence, albeit small, of patients who experience CH to such a degree that their lifestyle becomes significantly worse than what they experienced prior to operation and there is little that can be done for them. There have been attempts at reversal of the sympathicotom y with reanastomosis but this requires a technical tour de force and rarely is successful. Patients should be well informed prior to operation that it is highly likely they will experience some manifestation of CH and there is a small chance that it could be severe. Recognizing potential risk factors, as pointed out by Dr. Force, should ideally prompt a trial procedure such as the injection of local anesthesia to create a sympathetic block in an attempt to assess the likelihood of severe CH.

LRK
INTRODUCTION

Pectus excavatum (funnel chest) and pectus carinatum (keel chest) are the most common chest wall deformities. Pectus excavatum is an anterior chest wall deformity that presents as a posterior depression and frequently associated with rotation of the sternum and the lower costal cartilages. It occurs in up to 1 in 300 to 1 in 1,000 births with a 4 to 1 male predominance. Protrusion of the body of the sternum, pectus carinatum, presents less frequently than excavatum and occurs more commonly in boys as well. The etiology of the pectus anomalies has not been established but the association between pectus excavatum and other musculoskeletal abnormalities, particularly scoliosis and Marfan’s syndrome, suggests that abnormal connective tissue plays a role. A genetic predisposition is supported by a family history of chest wall deformities in approximately 40% of patients. The clinical presentation of pectus deformities varies from a noted depression or protrusion in the neonatal stage that persists throughout childhood and becomes progressive in adolescence. Most commonly, the pectus deformity becomes apparent and progressive with the onset of puberty and the axial growth spurt. Although there is limited physiological dysfunction noted during this initial timeframe, patients may become symptomatic from a cardiopulmonary perspective as they become more active. A universal concern of significance to all pectus patients is the cosmetic disfigurement, which is associated with a serious loss of self-esteem and can affect social behavior. The anterior chest disfigurement appearance becomes a major issue for adolescents at a time of great vulnerability during phases of puberty that is often characterized by excessive physical, social, and emotional changes. Patients with these deformities experience feelings of shame and try to hide their chests as reflected by their choice of clothing or body posture and avoidance of social activities and sports. This compounds the cardiopulmonary symptoms; patients become more withdrawn perhaps adding to their physical symptoms, which has been documented well beyond adolescence into adulthood. The purpose of this chapter is to review the indications for operative repair, to the preoperative evaluation, and to describe the common techniques for operative correction. The discussion focuses on the contemporary minimally invasive Nuss procedure, the classic open Ravitch procedure, and alternative procedures used for secondary operations and adult patients.

CLINICAL PRESENTATION

Children with pectus excavatum present with a wide spectrum of chest depression deformities from a mildly depressed sternum to a severe case in which the sternum almost abuts the vertebral bodies. The depression is created by two components. The first is posterior angulation of the body of the sternum beginning just below the insertion of the second costal cartilage. The second component is posterior angulation of the costal cartilages–sternal junction due to a seeming overgrowth and deformity of the costal cartilages. The sternum itself appears normal; the posterior angulation is due to the abnormal cartilage growth and position. The deformity maybe broad and shallow or narrow and deep, and asymmetry might exist as well. Pectus excavatum is generally well tolerated in infancy and childhood. Older children, however, may complain of pain in the area of the deformed cartilages or of precordial pain during or after exercise. Some patients might have palpitations, presumably transient atrial arrhythmias and might be associated with mitral valve prolapse. The physiologic impact of pectus excavatum has been the topic of much debate including the evolution of cardiopulmonary testing, which is well documented in the literature. Generally, this has included extensive pulmonary and cardiovascular function evaluation including echocardiographic studies. More recently, pulmonary function tests combined with exercise stress and metabolic testing have been employed, but not uncommonly no physiologic abnormality is detected. Provocative testing with exercise may be the most accurate way to determine the level, if any, of physiologic derangement. Pectus carinatum patients rarely are symptomatic, and no consistent abnormalities related either to cardiac or pulmonary function have been observed. Most commonly, carinatum deformities are less noticeable until adolescence and tend to progress during the pubertal growth spurt.

PREOPERATIVE EVALUATION

Parents bring their child for surgical evaluation at various times. Often, a young child will present with the congenital pectus variant without symptoms or cognitive psychosocial concerns. These patients and families need reassurance and careful follow-up on a yearly basis. Another time for surgical evaluation comes with the prepubertal and pubertal growth spurt. The axial growth during puberty is a common time for worsening of the pectus excavatum depression. The two most popular surgical corrections to date are the modified Ravitch procedure (open technique) and the minimally invasive repair made popular by Nuss (Nuss procedure). The popularity of the minimally invasive Nuss procedure and widespread usage of social media has brought many families and children in for early evaluation. The patient workup for each surgical approach can be assessed at the initial consultation and tailored based on the family’s concerns and intentions as well as their desire for one procedure over another and modified by the surgeon’s preference for surgical repair technique. In some centers,
the Nuss procedure, or some modification, is preferentially performed after the axial growth spurt has concluded. This allows for surgical correction of the deformity with minimal concern for recurrence from continued axial growth. Most often this procedure is performed in the mid-to-late teens. The Nuss procedure can be performed earlier, although not recommended to be performed too early, as continued growth after bar removal will create a similar pectus recurrence scenario. It is our practice to counsel families and patients about the timing of operation in the early-to-mid teens during the axial growth spurt if they are interested in the Nuss procedure as the duration of the bar placement is 2 to 4 years (Fig. 34.1).

For those patients with a mild-to-moderate deformity who are sedentary, it is recommended that an exercise program, improved posture, and breathing exercises be prescribed and patients are reevaluated at 6 to 12 months follow-up intervals. Patients with clinically severe deformities at initial presentations can be carefully evaluated with a three-step process.

In addition to a thorough history, physical assessment of symptoms, the initial consultation permits education about the operative options if indicated and allows one to gauge the sincerity of a family’s and child’s wishes to proceed with surgical correction. The preoperative workup includes cross-sectional imaging with computed tomography (CT) scan or magnetic resonance imaging (MRI) of the chest to calculate the Haller index, a measurement of pectus depression severity calculated by dividing the transverse thoracic distance by the anterio posterior (AP) distance from posterior sternum to anterior vertebral body, pulmonary function studies including spirometry, and cardiology evaluation including echocardiogram and electrocardiogram. More recently, pulmonary function testing and stress treadmill cardiac evaluation can be combined as a measure of metabolic function providing an index of baseline cardiopulmonary performance. Surgical correction is generally indicated if the patient presents with symptoms, has a severe pectus excavatum based on the clinical evaluation including CT or MRI, Haller index >3.2, evidence of cardiac or pulmonary compression on the CT, MRI, or echocardiogram, evidence of mitral valve prolapse, arrhythmia, or restrictive lung disease. An important additional criterion depending upon stage of pubertal development and social maturation is the degree of significant body image disturbance, which can influence both the child and family. A major consideration is the hesitation on the part of commercial payers to cover the cost of the pectus repair.

**SURGICAL CONSIDERATIONS**

In 1998, Nuss reported a “minimally invasive” correction of pectus excavatum by insertion of a convex steel bar under the sternum. The technique is possibly based on the malleability and flexibility of the anterior chest wall. Although it requires no cartilage incision or resection and no sternal osteotomy, it is a misnomer to consider it minimally invasive. This technique requires advanced skill, training, and careful pre- and intraoperative planning for successful outcome. It is of utmost importance to take a careful history including any allergy history to the components used in the traditional stainless steel bar. Should there be a history or family history of allergy to metal or Nickel, patch testing should be done. If an allergy is identified and confirmed, a titanium bar can be used instead of a stainless steel bar. The titanium bar, however, is not as malleable as steel and consequently must be bent at the factory with computer-assisted design manufacturing technology, which is readily available from the manufacturer. A copy of the patient’s preoperative axial cross-sectional imaging scanning can be provided. Titanium is approximately four times as expensive as steel and therefore should not be used for routine cases where metal allergy is not an issue. The correct size bar needs to be determined in advance and this is accomplished by measuring the distance from the mid-axillary to mid-axillary line across the deepest point of the depression. The bar needs to be 2.5 cm or 1 inch shorter than the distance from the right-to-left mid-axillary line. The correct size and shape of the bar are critical to success of the operation and resulting elevation of the sternum. The stainless steel pectus support bar is bent in the operating room at the time of the operation to conform to the patient’s chest configuration; conversely, the titanium bar needs to be present at the manufacturing facility based on the custom measurements.

A preoperative discussion with the patient and family regarding the postoperative pain management is crucial. This has been the topic of some debate as evidenced by numerous reports published in the literature, which favor epidural versus patient-controlled analgesia (PCA). The pain control strategy also needs to be
modified in consultation with the anesthesia and pain management specialists at each institution. It is our preference in consultation with the pediatric anesthesiologist ahead of time to consider a thoracic epidural; however, a one-time lumbar intrathecal injection of morphine has proven equally efficacious. We also favor PCA as this reinforces the motivated patient to be an active participant in their postoperative pain management and recovery.

**Nuss Procedure**

The operation is performed under general anesthesia (Fig. 34.2). Careful attention to pressure points and padding is essential and both arms are abducted comfortably so as not to cause injury. Some surgeons perform the procedure from the patients right to left, whereas others perform it from left to right. Moreover, other surgeons make a third incision in the subxiphoid region and apply a towel clip or a bone hook to help elevate the sternum for passage of finger or dissecting bar under the sternum. It is our practice once under anesthesia to measure the left-to-right mid-axillary distance again, to confirm the proper bar choice and then to bend the bar appropriately such that a slight overcorrection will be fashioned in the sternal region leaving a 2- to 4-cm flat section in the middle of the bar for sternal support. A 5.0-mm trocar is inserted either inferior to the site of bar placement or superior but in either position to allow for proper orientation and visualization of the mediastinum and passage of the bar across the mediastinum. Using CO₂ insufflation, a 5.0-mm, 30-degree scope will help accomplish this visualization and safety. Once the deepest portion of the pectus depression is appreciated, bilateral subcutaneous incisions can be created just off the mid-axillary lines and carried to the height of the pectoral ridges bilaterally. Employing unilateral thoracoscopy, the pectus introducer bar can be passed through the subcutaneous tunnel to the pectoral ridge and carefully introduced into the thoracic cavity under direct visualization (Fig. 34.3A–34.3F). At this point, the deepest portion of the sternum can be appreciated thoroscopically and a plane of dissection can be created in that location. Often the deepest portion of the sternal location is immediately adjacent to the pericardium. As an added safety maneuver, first, a transmediastinal tunnel can be created just superior to that deepest part of the deformity to aid in lifting the sternum off the cardiac structures. To minimize the risk of catastrophic mediastinal injury, specifically cardiac injury, we recommend that the tip of the pectus introducer bar be maintained under strict visualization at all times. A gentle sweeping technique helps facilitate separation of the subternal areolar tissue and advancement of the pectus bar while the thoracoscope allows careful visualization posterior to the sternum to the opposite hemithorax. Once the pectoral ridge on the contralateral side is reached and confirmed by the assistant, the pectus bar is then pushed out of the contralateral hemithorax and into the contralateral subcutaneous tunnel. At this point, the bar can be pushed completely across the mediastinum and the assistant surgeon can help elevate the sternum and anterior chest by simultaneously lifting the bar. Modifications of the technique involve the use of bilateral thoracoscopy or using a subxiphoid window in certain situations to help elevate the sternum for the dissection or passage of the bar. Although one support bar is used in the majority of cases, it is at this point of the procedure where one might decide a second bar would be necessary to more effectively elevate the deepest part of the sternum if less than a desirable amount of anterior movement has been accomplished, keeping in mind the bar must reside under the sternum and not the xiphoid. The assistant then ties an umbilical tape to the pectus introducer bar and under thoracoscopic guidance, the umbilical tapes are pulled backward through the substernal tunnel to the original site of introduction. The previously prepared definitive pectus support bar is then tied to one of the umbilical tapes and again under strict thoracoscopic visualization and guidance is drawn through the substernal tunnel with the convexity facing posteriorly. Once the bar is in position, it is then rotated 180 degrees using the bar flippers simultaneously on each side. The end of the bar is then inserted into the stabilizer, which fits perpendicular to the bar and is stabilized to the chest wall with a series of 0 PDS sutures or surgical steel wire placed in figure-of-eight fashion around the bar and stabilizer to include rib and fascia. This minimizes the chance of postoperative bar displacement as was experienced in the experience with the Nuss procedure when the stabilizer was not routinely used. Attention is then turned toward wound closure with careful consideration for hemostasis and multilayer closure of the deeper tissues over the bar followed by subcutaneous closure and finally cutaneous closure.

The Nuss procedure also may be employed for correction of a pectus carinatum deformity. As for the repair of the excavatum deformity following evaluation of the degree of the deformity, a stainless steel bar is bent appropriately so that it will

![Fig. 34.2. Illustration of the Nuss operative procedure.](image-url)
adequately depress the sternum deformity. The bar is placed through a subcutaneous tunnel and secured in place to the chest wall with stabilizers as described above. The bar should remain in place for at least 2 years according to those experienced with the Nuss procedure. The use of a dynamic compression system that uses a custom-made aluminum brace and avoids an operative procedure altogether also has been described for the treatment of the carinatum deformity. The brace simply pushes the deformity toward a more normal position over time, allowing bone reorganization to occur to allow the sternum to remain in the corrected position.

The Ravitch Procedure and Modifications
An alternative to the Nuss procedure and the procedure that has classically been described as the ideal repair for pectus excavatum deformity is the Ravitch procedure or some modification of this procedure that was originally described by Mark Ravitch. The classic Ravitch procedure involves bilateral subperichondrial resection of all deformed costal cartilages generally from costal cartilage 3 through 7 as well as an anterior wedge-shaped osteotomy to elevate the sternum. The sternal osteotomy is then supported with a retrosternal strut for 6 months to 1 year to secure it in a firm anterior position while the perichondrium heals and ossifies (Fig. 34.4).

**Technique**
A transverse incision is generally placed below and within the nipple lines at the site of the future inframammary crease. Skin flaps are then mobilized superiorly to just above the extent of the deformity using electrocautery to maintain meticulous hemostasis. The pectoralis major muscles are then reflected off the sternum and costal cartilages on both sides along with portions of the pectoralis minor. The correct plane can be challenging to identify; however, once the medial aspect of the muscle is separated using electrocautery from the sternal attachment, an empty knife handle can be used directly anterior to the costal cartilage to elevate the muscle. This is performed sequentially on all involved costal cartilages on both the right and left side, which then allows for placement of right angle retractors which are pulled anterior for additional exposure. Care must be taken to identify the proper avascular plane and avoid entry into the intercostal muscle bundles. This is not easy especially toward the upper costal cartilages, considering that one is working under a large skin flap that makes visualization and instrument placement
difficult. Rectus abdominis muscle insertions are also divided as needed to expose the inferior cartilages.

Once fully exposed, the subperichondrial resection of the costal cartilages can be achieved by incising the perichondrium anteriorly. A plane can be created between the perichondrium and costal cartilage allowing for complete subperichondrial resection. The difficulty is in establishing the correct plane since it is very easy to incise through the perichondrium and into the cartilage. The subperichondrial dissection is most easily done with a freer-type elevator commonly found on neurosurgical instrument sets. The edges of the incised cartilage should be grasped with mosquito clamps to provide countertraction to facilitate the dissection. The most difficult part occurs in coming around the curvature of the cartilage to carry the dissection posteriorly. Care should be taken to avoid penetrating the posterior perichondrium as this layer should remain in place. The cartilage must be disconnected from the sternum carefully by placing a perichondrial elevator posterior to the costal cartilage as it is divided sharply or simply disarticulated. This prevents injury into the mediastinum. The divided cartilage can then be held with an Alice clamp or similar instrument, elevated out of the perichondrial bed and the costal cartilage can be completely removed from the perichondrium at the costochondral junction. This is executed bilaterally from costal cartilages 3 through 7 and facilitated with the understanding that costal cartilage anatomy for numbers 3 and 4 are flat and broad, circular for numbers 4 and 5, and the 6th and 7th are generally narrow and deep. Depending on the extent of the deformity, it may not be necessary to remove every cartilage between the third and the seventh. Once complete subperichondrial resection of all involved costal cartilage is achieved and hemostasis is assured, a wedge osteotomy can be created anteriorly generally just above the level of the third costal cartilage, but more precisely above the level of the deformity so that the anterior movement allowed by the osteotomy corrects, and potentially even slightly overcorrects, the excavatum deformity. Two transverse sternal osteotomies are created through the anterior cortex so as to fashion a wedge osteotomy with the intervening wedge segment and the anterior cortex removed. The base of the sternum and rectus muscle flaps are elevated with towel clips, and the posterior plate of the sternum is fractured behind the wedge osteotomy. The size and shape of the xiphoid process determines whether all or a portion of it needs to be excised, the sternum is elevated anteriorly almost to overcorrection, and a retrosternal metal strut is placed posterior to the sternum to support and fix the sternum in the corrected position. The retrosternal strut is secured with sutures to the ribs bilaterally to prevent strut migration, and the anterior incisions of
the perichondrium can be closed with absorbable sutures though realistically many of these do not allow for closure. A suction drain is brought through the inferior skin flap and placed in a parasternal position prior to the pectoral muscle flaps being secured back to the midline position on the sternum. Usually, a second suction drain is placed under the skin flap and the skin is then closed in layers with absorbable suture and a cosmetic subcuticular skin closure completes the procedure. The suction drain is removed once the drainage is $< 15 \text{ ml}$ over an 8-hour shift. The retrosternal struts are generally removed 6 to 12 months after repair, which allows for enough time for solid fixation of the sternum in the correct position and for fibrosis of the chest wall where the subperichondrial resection of cartilage were carried out. The retrosternal strut or struts are removed generally as an outpatient procedure through small lateral incisions placed over each end of the strut.

In this period of time, the retrosternal metal strut that is in place differs significantly from that required with the Nuss procedure, where the retrosternal stainless steel bar is required to remain in place for 2 to 4 years to allow for costal cartilage and chest wall remodeling.

A modification of the Ravitch procedure initially described by Eric Fonkalsrud involves much more limited cartilage resection significantly reducing both the time and extent of the operative procedure. This modification requires only that small pieces of parasternal and costochondral cartilage be removed in a subperichondrial fashion as opposed to the entire costal cartilage at each level. This limited cartilage resection accomplishes the same purpose in that it allows for the sternum to be completely mobilized and elevated anteriorly achieving the desired correction once an anterior wedge osteotomy is made. In addition, the medial and lateral resection of pieces of cartilage at each level allows the cartilages to “drop back” to a normal anatomic location. The carinatum deformity may also be corrected using this technique. In these patients, once the limited cartilage resection is done at each level a simple transverse osteotomy is made across the anterior sternum at the desired level, and a wedge of autologous costal cartilage is placed within the osteotomy to depress the sternum to the desired location.

When correcting an excavatum deformity once the sternum is elevated anteriorly, a metal strut can be placed retrosternally to hold the corrected sternal position in place and subsequently removed in a minor procedure 1 year later as described above. Similarly, to stabilize the repair for a carinatum deformity a sternal bar is placed on the now posteriorly located sternum and a suture placed through the sternum and attached to the bar. Alternatively, modern orthopedic fixation using low profile plates and screws may be used for sternal fixation in either excavatum or carinatum deformities, thus avoiding the need for placement of a bar that needs to be removed. Several systems exist for this type of fixation specifically those designed for sternal closure following standard median sternotomy (SternaLockBlu system, Biomet, Inc. Warsaw, IN).

### POSTOPERATIVE MANAGEMENT

In conjunction with our pediatric anesthesiologists, it is our preference to perform a one-time lumbar intrathecal injection of morphine at the time of operation. Patients are extubated in the operating room and recovered in the intensive care unit for the specific purpose of maintaining optimal pain control and relaxed breathing. Our general pain management strategy combination includes a narcotic, an anti-inflammatory, and a muscle relaxant. Initially, pain control is maintained with continuous and demand PCA narcotic infusion. Patients remain on bed rest immediately postoperatively with the head of the bed elevated. On postoperative day 1, the anti-inflammatory analgesic, Ketorolac (Tora-dol), and muscle relaxant cyclobenzaprine (Flexeril) are added to the pain control regimen. For patients not tolerating a clear liquid diet, IV dexamethasone may be substituted for the oral muscle relaxant, if necessary. Patients are given strict instructions regarding bending at the waist only and are out of bed to a chair and ambulate with assistance at least 3 times daily. Incentive spirometry use is encouraged every hour while awake and remains mandatory. The oral diet is advanced as tolerated. By postoperative day 2 to 3, as diet is advanced, the oral combination acetaminophen and hydrocodone (Vicodin) is instituted and the demand or continuous infusions of narcotic is weaned. Ibuprofen is substituted for the Ketorolac. Physical activity in the hospital, initially under the supervision of a physical therapist, is progressive but limited by bending at the waist and consists of regular ambulation including stair climbing and a range of motion exercises of the arms and shoulders. Movement strategies to promote comfort at home are taught. Patients are discharged home with the combination of an oral narcotic analgesic, a nonsteroidal anti-inflammatory agent, a muscle relaxant, and a stool softener to assure analgesia and comfort is adequately addressed. Deep breathing exercises and incentive spirometry continues at home as does regular ambulation and use of stairs. Patients and parents are instructed to limit all strenuous activity, including strenuous exercise, bending, and/or lifting object from the floor. The wearing of backpacks is initially prohibited. Our length of inpatient stay averages between 5 and 7 days and the first outpatient visit generally occurs around postoperative day 14. At that time, pain control and range of motion are assessed and adjusted. Oral narcotics, muscle relaxants, and anti-inflammatories are weaned as tolerated, and specific exercises designed to increase the range of motion are advanced.

### COMPLICATIONS

Complications resulting from either surgical approach should be rare but include wound infection and pneumothorax. The most frustrating complication resulting frompectus repair is recurrence of the deformity. In large series with adequate follow-up, recurrence is reported to occur as frequently as 5% to 15%. Progressive deterioration of the repair overtime is described particularly during the interval of rapid growth at puberty, if the operation has been performed too early in younger patients. The use of strut fixation and bone stabilizers to avert migration and displacement of the bar with growth and delaying repair until the child is well into pubertal growth spurt might help delay or avoid recurrence (Figs. 34.5 and 34.6). Growth of the chest wall during pubertal and axial growth spurt while the bar is in place may also aid in remodeling the anterior chest wall and thoracic cage and prevent subsequent recurrence. Rigid fixation is uniformly applied in patients with Marfan’s Syndrome because of their well-recognized high risk of recurrence.

A summary of complications resulting from the minimally invasive Nuss procedure is noted in Tables 34.1 and 34.2. Early complications include pneumothorax and hemothorax, well recognized in this group. Late complications are minimal but are generally associated with bar displacement most of which occurred prior to the use of bar stabilizers that fixate the bar to the chest wall. Several studies have been published that attempt to evaluate both the minimally invasive Nuss and open Ravitch procedures both in terms of outcomes and specifically looking at complications. A 2010 meta-analysis performed by Wales et al.

employed a systematic review to compare complication rates from both the Nuss and Ravitch procedures. This paper found nine noncontrolled studies (eight retrospective cohort series) and one prospective study published between 2001 and 2009 that directly compared the open Ravitch operation with the minimally invasive Nuss procedure. Overall, there was no difference noted between the techniques with regard to overall complication rates. Secondary outcomes such as duration of hospitalization, duration of surgery, time to ambulation, postoperative pain management, and patient’s satisfaction were assessed and demonstrated a procedure-specific complication profile.

Specific complications, such as rate of reoperation was higher after the Nuss procedure compared to the Ravitch procedure and related mainly to bar migration particularly in the era prior to bar stabilizers being routinely used. Bar migration has been significantly diminished with the widespread usage of bar stabilizers. Postoperative pneumothorax and hemothorax occurred with slightly greater frequency in the Nuss group; however, there was no difference between the two groups in requirement for blood transfusion. The operative duration was nearly 70 minutes longer in the Ravitch group. There was no difference with regard to length of hospitalization or time to ambulation. Postoperative pain management strategies were
numerous and thus pain-related complications are very difficult to ascertain. Combinations of intravenous, oral, and epidural analgesia were used with similar results. Finally, only two studies used any sort of assessment to measure patient satisfaction. Unfortunately, they used different instruments to assess satisfaction and thus a definitive conclusion remains difficult. Recently, investigators associated with the Nuss group published their patient satisfaction surveys as part of their 21-year experience that includes nearly 800 patients who completed over 1,400 surveys. Over 90% of patients reported that they were either “very happy” or “happy” with their results. Only 1% of patients were “not at all happy” and over 90% of parents were “very happy” or “happy” with their child’s outcome.

SUGGESTED READINGS

EDITOR’S COMMENTS

The authors have described a learned approach to chest wall deformities. They have done an excellent job at discussing the two major procedures done. There certainly has been a lot of interest in the minimally invasive Nuss procedure. However, the recurrence rate is high for this procedure and the bands need to be placed for a significant period of time. The discussion about the specific technologic aspects of both repairs certainly gives the reader an opportunity to understand the best approach for an individual patient.

An area that was not discussed occurs fairly commonly in my practice. Patients with Marfan syndrome often have chest wall deformities and aortic dilation. This needs to be taken into account prior to the chest wall procedure. Our preference is to fix the aortic root if needed prior to any major sternal procedure. In addition, one has to be very careful in these patients in terms of preventing cardiac compression after closure of the deformed sternum.

ILK
Repair of Paraesophageal Hernia
Arjun Pennathur, Matthew J. Schuchert, and James D. Luketich

INTRODUCTION
Paraesophageal hernias represent subtypes of hiatal hernia. The most common form of hiatal hernia is the simple or sliding (type I) hiatal hernia (95%), in which the gastroesophageal (GE) junction migrates above the diaphragmatic hiatus, frequently associated with incompetence of the lower esophageal sphincter (LES). The remaining forms of hiatal hernia can be classified as paraesophageal (5%). Type II paraesophageal hernias are rare but are characterized by the position of the GE junction below the diaphragm, with a portion of the fundus and greater curvature of the stomach migrating through a hiatal defect alongside the esophagus. In type III paraesophageal hernias, the GE junction and fundus are displaced superiorly, with protrusion through a hiatal defect (Fig. 35.1). Type IV hernias are defined as herniation of the entire stomach, omentum, and/or other intra-abdominal organs such as the transverse colon, and spleen into the mediastinum. The characteristic anatomic defects of paraesophageal hernias include enlargement of the diaphragmatic hiatus and abnormal laxity of the gastrosplenic and gastrocolic ligaments, allowing migration of the stomach (and other abdominal contents) into the chest. Giant paraesophageal hernias (GPEHs) are defined by the presence of greater than one-third of the stomach within the chest.

The actual incidence of paraesophageal hernia is unknown. It is estimated that paraesophageal hernias make up 3% to 15% of all hiatal hernias, producing an estimated incidence of 15 to 45 per 100,000 individuals within the general population. Symptoms of paraesophageal hernia frequently include obstructive symptoms, such as dysphagia, and reflux symptoms (heartburn, regurgitation, etc.). Chest pain (especially postprandial) is a common finding and is frequently mistaken for anginal symptoms. Postprandial distress, nausea, bloating, and anemia are also commonly encountered. A relatively asymptomatic but insidious symptom is occult gastrointestinal bleeding. Anemia is reported in 20% to 30% of patients with paraesophageal hernias in published series, but the rate of blood loss is slow and is rarely associated with hemodynamic compromise. A significant fraction of patients with paraesophageal hernia are asymptomatic or complain of only minor symptoms. The exact proportion of such patients is difficult to estimate for obvious reasons. Interestingly, it has been estimated that up to 89% of patients denying symptoms will actually describe some symptoms when questioned carefully.

Symptoms can be progressive, however, and can potentially result in catastrophic complications. Mortality from strangulation may be >50%, depending on the patient’s age and the potential for delay in diagnosis. This has led many to argue that symptomatology is not a reliable predictor of who might progress to acute complications, and that elective surgery should be performed on most patients with a GPEH, in particular, those with organoaxial rotation as seen on a barium esophagram. Prompt elective repair after diagnosis has been recommended to avoid the development of such complications. When the repair is performed electively, excellent control of symptoms (>90%), with a low perioperative mortality of <1% to 2%, can be achieved.

Despite the foregoing observations, the beliefs held by surgeons are still largely based on small patient series and anecdotal case reports. There is little doubt that patients presenting with obstructive symptoms, bleeding, or both should undergo elective hernia repair. However, surgical correction of truly asymptomatic or minimally symptomatic paraesophageal hernias is controversial. Some studies suggest that asymptomatic patients have an 85% annual probability of remaining asymptomatic. This implies that about one in six patients will develop new symptoms, which can then be treated with elective repair. The probability that a patient’s initial presentation would require an emergency operation has been estimated to be only 1% per year. Although mortality of an emergency operation has been reported as high as 50%, a pooled analysis of the largest series demonstrated an aggregate operative mortality rate of 17%. In a larger analysis of a nationwide database, the mortality rate for emergency operation for paraesophageal hernia (n = 1035) in 1997 was only 5.4%. Thus, for a 65-year-old asymptomatic patient, who has an 18% lifetime risk of developing life-threatening symptoms (1% per year) requiring emergency surgery (5.4% mortality), the overall lifetime risk of death with observation is approximately 1%, comparable to the expected 1% to 2% mortality of elective repair. Decision analysis models have failed to demonstrate a gain in quality-adjusted life expectancy with elective laparoscopic repair of asymptomatic paraesophageal hernias when compared with watchful waiting.

When symptoms arise, the only effective treatment of paraesophageal hernias is surgical repair. The surgical technique involves reduction of the herniated contents back into the abdomen, excision of the hernia sac, and closure of the hiatal defect. These procedures can be performed transthoracically or transabdominally with laparotomy or laparoscopically. In extremely high-risk patients with minimal symptoms, an anterior gastroectomy can be performed to help prevent the development of incarceration or organoaxial volvulus. In the absence of reflux symptoms, the need to perform an antireflux procedure has been debated. However, up to 60% of patients with type III hernias have also been shown to have hypotensive LES pressures and abnormal 24-hour pH-monitoring studies. In addition, with the repair of large paraesophageal hernias, there is significant dissection performed around the hiatus, the phrenoesophageal ligament is divided, and the lower esophageal antireflux mechanism is affected; thus, many surgeons (including us) recommend routinely performing an antireflux procedure during elective repair. The use of partial (Belsey, Dor, and Toupet) or complete (Nissen) wraps has been reported, each with good results. The choice of wrap is determined by the individual patient’s underlying anatomy.
Section I: General Thoracic Surgery

PREOPERATIVE EVALUATION

Preoperative assessment includes a barium esophagram in order to definitively establish the diagnosis (Fig. 35.1). The barium esophagram is a critical component of evaluation and demonstrates the paraesophageal hernia; it can also give an estimation of esophageal length in addition to providing information on the presence of strictures or other sequelae of GE reflux. Upper endoscopy is also critical and allows assessment of the gastric anatomy, location of the GE junction, assessment for short esophagus (Fig. 35.2), esophagitis and other complications of reflux disease, and potentially excludes other abnormalities such as Barrett’s esophagus, or neoplasia. It is also important to consider performing esophageal function studies. Esophageal manometry can be particularly useful for the evaluation of esophageal motor function, the presence of peristalsis, evaluation of the amplitude of contractions, and may influence the choice of fundoplication; in addition, it may allow the assessment of esophageal length (Maziak et al.,). However, it should be noted that manometry and 24-hour pH studies may not be feasible because the degree of anatomic distortion frequently interferes with the reliable performance of these studies. When performed, it should be done with caution in view of the anatomic distortion, and in a few centers the catheter is placed with endoscopic guidance. Patients also undergo a complete cardiopulmonary evaluation for clearance and risk assessment prior to repair of the paraesophageal hernia. Active pulmonary infection is treated prior to surgery, and patients are advised to stop smoking.

SURGICAL APPROACHES

Traditionally, the repair of a GPEH has been performed through an open laparotomy or thoracotomy. Increasingly, the repair of GPEH is being performed using minimally invasive techniques with a laparoscopic approach. In this chapter, we discuss the laparoscopic approach and the transthoracic approach for repair of GPEH.

Laparoscopic Repair of Giant Paraesophageal Hernia

In the operating room, after intubation, we start with the esophagogastroduodenoscopy (EGD) performed by the surgeon for confirmation of previous endoscopic findings. It is important not to insufflate too much air at the beginning of the procedure, since this will interfere with the laparoscopy. Standard laparoscopic port placement is used as shown in Figure 35.3. To facilitate the ease of mediastinal dissection, the abdominal port incisions can be shifted slightly cephalad in the case of a GPEH. The left lateral segment of the liver is retracted anteriorly with a 5 mm flexible retractor (Snowden Pencer, Genzyme, Tucker, GA) and secured to a stationary holding device (Mediflex, Islanda, NY). Dissection is begun by identifying the sac, dissecting the sac, and subsequently inverting the mediastinal hernia sac and pulling it back into the abdomen along with the herniated stomach (Fig. 35.4). Avoidance of direct traction on the stomach by using a “hand over hand” technique results in less trauma to the stomach.
while reducing the herniated intrathoracic stomach. The crural reflection of the sac is incised, and the flimsy mediastinal attachments to the sac are carefully taken down by the harmonic scalpel (Ethicon, Cincinnati, OH) or the ultrasonic shears (U.S. Surgical Corp, Norwalk, CT). (Fig. 35.5). Care is taken to identify and preserve the proximal anterior and posterior vagus nerves during this portion of the dissection. Similarly, the adjacent pleura must be identified and swept laterally away from the plane of dissection. The surgeon and the anesthesiologist must communicate closely during this portion of the procedure because a sudden drop in blood pressure or significant increase in inspiratory pressures may indicate the development of a tension pneumothorax, which can be readily treated by placement of a pigtail catheter or a chest tube. Once the sac is completely freed up, along with the contents, is reduced back into the abdomen and the redundant sac may be carefully excised avoiding injury to the vagi (Figs. 35.5 and 35.6). The complete dissection and reduction of the hernia sac with its contents from the chest to the abdomen is a critical component of successful surgery for GPEHs. With the delivery of the sac into the abdomen, the herniated stomach (and other herniated intra-abdominal structures) is reduced back into the peritoneal cavity. This portion of the case is also critical in achieving maximal esophageal mobilization and a tension-free repair. Inferior traction on the gastric fundus and epiphrenic fat pad is then performed to allow complete dissection of the right and left crus. A retrogastric/retroesophageal window is then created to expose the posterior portion of the left crus. At this point, the division of the short gastric vessels is performed in order to fully mobilize the fundus of the stomach.

**Assessment of Short Esophagus**

In the setting of a GPEH, careful identification of the GE junction after fat pad excision frequently reveals a shortened esophagus. The esophageal fat pad is carefully and completely mobilized medially, sweeping the anterior vagus to the right of the esophagus (Fig. 35.7). The distal esophagus is then mobilized at the level of the diaphragmatic hiatus circumferentially, and the surgeon then determines whether esophageal shortening is present. The proper assessment of esophageal length can be tricky because there is a tendency to overestimate the intra-abdominal length of the esophagus because of the diaphragmatic elevation caused by the pneumoperitoneum as well as the downward traction that is applied to the stomach. If the GE junction does not remain below the diaphragmatic hiatus with an adequate segment of tension-free intra-abdominal esophagus (ideally 2 to 3 cm), then further mediastinal mobilization of the esophagus should be performed, extending higher into the mediastinum to the inferior pulmonary vein, and in extreme cases, the dissection can be carried significantly higher if needed to gain additional esophageal length. The esophageal length should again be reassessed, with the goal of an adequate, tension-free intra-abdominal esophageal segment of 2 to 3 cm. If after extensive mediastinal mobilization, there is inadequate esophageal length, we then perform a Collis gastroplasty prior to fundoplication. This can be done with an end-to-end anastomosis (EEA) stapler (Figs. 35.8-35.10) or a GIA stapler. At present, we prefer to perform the Collis gastroplasty with a wedge gastroplasty technique, using a GIA stapler (Figs. 35.11 and 35.12).

As mentioned earlier, we routinely perform a fundoplication to prevent reflux since it is highly likely that the preceding dissection has disrupted the function of

![Fig. 35.4. Reduction of the hernia sac without direct grasping and traction on the stomach itself.](image-url)

![Fig. 35.5. Complete reduction of the herniated stomach back in the abdomen, with complete reduction of the hernia sac.](image-url)
Section I: General Thoracic Surgery

The choice of the type of fundoplication depends on the results of physiologic testing. In general, we prefer a floppy Nissen fundoplication (Fig. 35.13).

This is performed after the surgeon places an esophageal bougie (54F), with direct laparoscopic vision of the distal esophagus, the GE junction, and the stomach. A floppy Nissen fundoplication is performed, and the bougie is removed. In brief, after complete mobilization of the distal esophagus and stomach, and determination of the location of the GE junction after dissection of the GE fat pad, an atraumatic instrument is passed in the retroesophageal window. The fully mobilized fundus is grasped and brought through the retroesophageal window with proper orientation. When the fundus is fully mobilized, there should be no or minimal tension and no tendency for the fundus to retract back through the retroesophageal window. A “shoe shine maneuver” is then performed to evaluate the tightness of the wrap, its mobility, and length. Subsequently, a floppy Nissen fundoplication is performed with space behind the wrap and the esophagus to allow the passage of an atraumatic instrument. Both the Collis gastroplasty and the fundoplication may be omitted in some high-risk patients, and instead a gastropexy is performed to anchor the stomach to the abdominal wall. While some have performed this as a single point or with the placement of a gastrostomy tube, we perform the gastropexy with several interrupted heavy mattress sutures anchoring the stomach to the diaphragm and the anterior abdominal wall. We start these sutures anchoring the stomach to the left crura and then to the anterior abdominal wall.

Approximation of the Crura

During the dissection, it is critical to maintain the peritoneal lining in an effort to preserve the integrity of the crura, and fully mobilize the crura. The crura are fully mobilized by dividing the phrenogastric, phrenosplenic, and retrogastric attachments. This mobilization, along with complete mobilization of the hernia and sac, allows the crura to be approximated primarily without excess tension in most cases. In some patients where crural tension is still present, inducing a small, left-sided pneumothorax may yield a “floppy diaphragm sign”, which allows a much easier tension-free primary repair. This should be done in close coordination with anesthesia, and subsequently, the surgeon can place a small pigtail catheter and eliminate the pneumothorax. This catheter can then be removed.
very early in the postoperative course. In unusual cases of an excessively large defect, a patch of Surgisis (Cook, West Lafayette, IN) is used to reinforce the closure. The crura are reapproximated posteriorly to complete the surgical procedure. The crural repair is performed with typically two or three heavy nonabsorbable braided sutures (0 Surgidac) placed posteriorly. We do not routinely use pledgets for the crural repair. We then reassess the hiatus, and if there is a significant anterior space and the hiatus appears wide, we place crural sutures anteriorly. The hiatus is reevaluated and the surgeon should be able to easily introduce the grasper with a 1 cm gap between the esophagus and the crura, with care being taken not to cause excessive narrowing of the hiatus, which may result in postoperative dysphagia.

Before closing, endoscopy is routinely performed with intraluminal insufflation to rule out esophageal or gastric leaks. A nasogastric tube is carefully placed under direct laparoscopic guidance. A barium swallow is obtained on postoperative day 1 to evaluate the repair and verify the absence of a leak; the nasogastric tube is typically removed on postoperative day 1. If no leak is present, clear liquids are started. If a clear liquid diet is tolerated, the patient is usually discharged to home on postoperative day 2. Advancement to a soft diet occurs over the subsequent 1 to 2 weeks.

**Transthoracic Repair of Giant Paraesophageal Hernia**

While our current primary approach for primary elective repair of paraesophageal hernia is a transabdominal laparoscopic approach, a transthoracic approach is favored by some surgeons and is a well-established technique (Maziak, Pearson; Patel, Orringer; Altorki, Skinner). The transthoracic approach is a particularly useful approach in patients with a long-standing GPEH, and those who may have a “hostile” abdomen due to multiple previous surgeries. It is useful in patients who have had multiple previous transabdominal anti-reflux procedures, or who have a recurrent paraesophageal hernia. The work-up for the patient who is being evaluated for a transthoracic approach is similar to that for the laparoscopic approach described earlier. A relative contraindication is previous left thoracotomy for inflammatory diseases such as empyema treated with decortication.

In particular, for those patients who are being evaluated for a revision procedure due to recurrent paraesophageal hernia, a complete and comprehensive work-up should be undertaken. In these patients, the original indication and history along with the operative report should be thoroughly reviewed. Specific attention should be paid to the definition of the GE junction, dissection of the fat pad, preservation of the vagi, closure of the crura, size of the bougie, and the technical details of construction of the fundoplication itself. To summarize, as detailed above, our work-up generally includes EGD and barium swallow. We also obtain manometry and pH monitoring when feasible. In patients requiring redo surgery, a gastric emptying study is also typically obtained to evaluate the functional integrity of the vagus nerves.

Operative Technique

The operative technique described here is based on the technique described by Pearson and colleagues. An epidural catheter is placed to optimize postoperative pain control and a left thoracotomy is planned. The patient is intubated with a double-lumen endotracheal tube. Adequate venous access is established, and a Foley catheter and an arterial line are also placed. An on-table EGD is then performed by the surgeon. Specific note is made of hiatal hernia, esophageal length, Barrett’s esophagus, esophagitis, and any other sequelae of reflux disease. The patient is placed in the right lateral decubitus position, pressure points are padded, and sequential compression devices are placed on the lower extremities. A posterolateral thoracotomy is then performed and the chest is entered through the seventh intercostal space. The latissimus is divided while the serratus is preserved. We excise a 1 cm segment of the eighth rib posteriorly. After placement of the rib spreader, the ribs are separated to a minimal extent as a 5 cm opening is usually adequate for exposure.

With isolation of the left lung, the lower lobe of the lung is retracted superiorly and the inferior pulmonary ligament is divided. The paraesophageal hernia contents enclosed by the sac are clearly visible. The mediastinal pleural overlaying the esophagus is opened starting from the level of the inferior pulmonary veins and extending inferiorly.

The vagi are identified here and preserved for the remainder of the dissection. The esophagus is dissected superiorly away from the sac and encircled with a Penrose drain, which is placed after circumferential mobilization, encompassing the esophagus along with the vagus nerves and this drain can be used for traction as the esophagus is mobilized (Fig. 35.14). The mobilization of the esophagus can be extended superiorly to the aortic arch. The next step is the dissection of the sac. In long-standing hernias, there may be dense adhesions between the sac and the pericardium and the lung. The sac is dissected and the adhesions between the sac and the pericardium are divided. Care must be exercised while retracting the pericardium, and hemodynamics should be monitored closely. It is best not to grasp the pericardium but use gentle traction during this dissection. The hernia sac is dissected away from the pericardium and the contralateral hemithorax, with care to avoid entry into the right pleural space. The hernia sac dissection is carried inferiorly around the hiatus and the hiatal defect is defined. Inferiorly, the esophagus is dissected between the hiatus and the inferior pulmonary vein by freeing up the mediastinal attachments. It is important to mobilize the esophagus along with vagi, with special care taken not to injure the vagi. Similarly, when dissecting the sac, one has to be careful not to injure the vagi.

After the dissection of the sac, the sac may be entered near the hiatus, and adhesions between the sac and the stomach

Fig. 35.14. All transthoracic fundoplications are preceded by the placement of crural stitches, which are left untied until the fundoplication wrap is completed. The fundus of the stomach is brought posterior to the esophagus in preparation for a Nissen fundoplication.
divided. The sac is opened in a circumferential manner anteriorly to posteriorly around the hiatus, adhesions within the sac divided, and the sac dissected completely off the stomach and GE junction. It is again important to emphasize the careful preservation of the vagus nerves during the dissection of the sac. In a moderate-to-large hernia, after complete dissection of the sac, the sac is excised.

The hiatus is then defined, and enlarged if needed, so as to be able to reduce the stomach along with the planned fundoplication into the abdomen. The esophagus is then freed up from the diaphragmatic hiatus to the inferior pulmonary vein. If there is tension noted when the stomach and the GE junction are reduced into the abdomen and a shortened esophagus is suspected, the esophagus should be mobilized to the level of the aortic arch. This requires ligation or cauterization of aorta–esophageal branches as the esophagus is fully mobilized. It is important to have a tension-free intra-abdominal segment of the esophagus (at least 2 to 3 cm) to assure a successful and durable repair. If there is persistent esophageal foreshortening despite complete mobilization of the esophagus, a Collis gastroplasty is performed prior to the fundoplication. In large series, the type of fundoplication described when using a transthoracic approach include a Belsey partial fundoplication (Pearson) and a transthoracic Nissen fundoplication (Orringer).

Defining the Gastroesophageal Junction, Mobilization of the Gastroesophageal Junction, and Mobilization of the Stomach
In moderate-to-large hernia, the sac is excised. The retroperitoneal attachments are then divided to mobilize the GE junction. An inconstant artery (“Belsey’s Artery”) communicating between the left gastric and the inferior phrenic arteries should be divided. This is typically encountered in the posteromedial dissection, and it is important to control these vessels before division. The crural decussation and crural defect are then clearly exposed.

The GE junction fat pad is then dissected along with left vagus nerve and mobilized anteriorly, and the GE junction is defined. The superior short gastric vessels are then divided to mobilize the gastric fundus, particularly if a Nissen fundoplication is planned. It is important to adequately mobilize the fundus so as to prevent any tension during construction of the fundoplication. At this stage, it is also important to make an assessment of esophageal length and assess whether a tension-free fundoplication can be performed. After reduction of the hernia, there should be a minimum of at least 2 to 3 cm of intra-abdominal esophagus without any tension. As mentioned above, if there is any concern for esophageal shortening, complete mobilization of the esophagus should be performed; a Collis gastroplasty should be performed if there is noted a tendency for the GE junction to migrate back into the chest after complete mobilization.

Esophageal Shortening and Collis Gastroplasty
If there is esophageal shortening despite esophageal mobilization, a Collis gastroplasty is performed. This is performed after careful placement of an esophageal bougie, with the bougie traversing the GE junction extending into the stomach. The greater curvature of the stomach is then grasped with a Babcock instrument and subsequently an endo-GIA stapler is applied and fired, immediately adjacent to the bougie tight to the lesser curvature of the stomach (Figs. 35.15 and 35.16). The staple line is then oversewn with continuous absorbable 3-0 sutures along the esophageal side without inverting the staple line so that the esophageal lumen is not compromised; the staple line is inverted with continuous sutures on the gastric side of the staples.

Placement of the Crural Sutures
The crural edges are clearly defined. The retraction of the stomach and the GE junction facilitates crural exposure. Generally, 0 silk nonabsorbable sutures are placed 1 cm apart in the crura. Typically, three to four sutures are placed posteriorly but not tied at this time. When there is a large hiatal defect, a couple of sutures may be placed anteriorly, so as to avoid excessive angulation of the esophagus by the placement of several posterior sutures. These crural sutures are all placed, clamped with hemostats, but not tied (Fig. 35.14).

Fundoplication
A Belsey partial fundoplication or a Nissen fundoplication is then performed. While Pearson and colleagues prefer a Belsey fundoplication, Orringer and colleagues have preferred a Nissen fundoplication.

For the Belsey fundoplication, the stomach is mobilized posteriorly into the chest, and a 54F bougie is then placed in the esophagus across the GE junction; this should be placed by the surgeon carefully under direct visualization. A 240- to 270-degree wrap is then performed as below (Figs. 35.17–35.19). The first row of mattress sutures is placed with 2-0 silk on an atraumatic needle. A total of three mattress sutures are placed in each row.

![Fig. 35.15. A Collis gastroplasty is created by firing a staple parallel to the lesser gastric curvature, snugly placed against a bougie that has been positioned across the esophagogastric junction. 4-5 cm of neoesophagus is typically created by the gastroplasty (Inset).](image-url)
The staple line of the gastroplasty is oversewn as described in the text, creating an extended esophagogastric tube and enlarging the gastric fundus.

A Belsey fundoplication is begun by mobilization of the upper stomach into the chest. The initial row of three mattress sutures incorporates 1 cm of stomach and 1 cm of esophagus and is evenly spaced between the vagus nerves. The untied previously placed crural sutures are also shown.

The first row of mattress sutures is then placed incorporating the esophagus, the stomach, and the diaphragm. These sutures are again placed in a similar manner, about 1 to 1.5 cm proximal and distal to the first row in the esophagus and the stomach. It is important to avoid placing the sutures in the fundus too far apart. A modified teaspoon is then placed through the hiatus to protect the abdominal viscera, and the suture is passed through the diaphragm. These sutures are placed but left untied. The partial Belsey wrap is then gently reduced into the abdomen, the sutures are pulled up tight, removing any redundancy in the sutures, and then tied. A modification of this technique is to tie the second row of sutures after the placement of the esophageal and gastric sutures, but leave the suture ends long with the needle intact (or alternately the suture can be rethreaded into a needle). The fundoplication is then gently reduced back into the abdomen manually. The suture needles are then passed through the diaphragm with a rim of 1 to 2 cm, with a modified teaspoon in place to protect the viscera, and this suture is then tied. If a Collis gastroplasty is performed, three rows of sutures are required for the Belsey fundoplication. In this case, the third row of sutures is used to anchor the fundoplication to the diaphragm (Fig. 35.20).

If a Nissen fundoplication is planned, the fully mobilized gastric fundus, after the division of the short gastric vessels, is delivered into the chest. The decision on the use of the Collis gastroplasty is made as detailed previously. A 54F esophageal bougie is placed by the surgeon so that the bougie traverses the GE junction and the tip is positioned in the stomach. The fundus is then passed posteriorly, and a lack of tension is assured. The fundoplication is then performed with three sutures, 1 cm apart to form a 2 cm fundoplication. These sutures incorporate the fundus on the left of the esophagus, the esophageal wall, and the fundus on the opposite side (right side) of the esophagus. All these sutures are placed and then tied (Fig. 35.21). The fundoplication is then reduced into the abdomen prior to tying the crural sutures. The Nissen–Collis repair is shown in Figure 35.22.
Approximation of the Crura

The crural sutures are then tied, starting with the most posterior suture. Care must be taken to avoid making the repair too tight and this should be calibrated. After the crural sutures are tied, the index finger should be able to slide easily along the posteromedial aspect of the crus. A nasogastric tube is then placed and guided into the stomach by the surgeon. A 28F thoracostomy tube is placed to drain the pleural space. The thoracotomy incision is then approximated in layers.

It is important to prevent retching or vomiting in the postoperative period and to that end antiemetics should be given prophylactically. The nasogastric tube should be functional to avoid postoperative gastric distension. The patency and function of the nasogastric tube should be assured by the staff. We obtain a follow-up barium swallow and if no abnormalities are seen, and the nasogastric tube drainage is low, the nasogastric tube is removed. The patient is subsequently started on clear liquids and typically discharged on a soft diet. Stool softeners are prescribed while the patient is taking pain medications. Patients are specifically instructed not to lift weights >10 lb or strain for a minimum of 2 months.

RESULTS OF LAPAROSCOPIC REPAIR

Although laparoscopic Nissen fundoplication has become a well-established procedure in the treatment of GE reflux disease (GERD), laparoscopic management of GPEHs has been somewhat controversial. Although early studies of laparoscopic repair of GPEH were promising, concerns have been raised about the safety and efficacy of a minimally invasive approach in handling this complex problem. Dahlberg reported the Mayo clinic experience in 37 patients undergoing laparoscopic repair of GPEH. Successful repair was accomplished laparoscopically in 35 of the 37 patients. Intraoperative complications included two splenic injuries and one crural tear. Postoperatively, there were two cases of esophageal leak and one small-bowel obstruction at a port site. Mortality was 5.4%. In short-term follow-up, 4 of 37 patients (12.9%) developed recurrent paraesophageal herniation. It was concluded that laparoscopic repair of GPEH is a technically challenging operation associated with significant morbidity and mortality. Similar results were obtained in a series of 60 patients by Weichman. In this series, reoperation for recurrent herniation was required in 5.5% of patients, with an associated 1.9% mortality. This study also concluded that laparoscopic repair of GPEH is a technically challenging procedure, but that with increasing experience and technical refinements, results could approximate those of the open approach.

As surgeons have gained experience with advanced laparoscopic techniques, improved results after laparoscopic repair of GPEHs have been observed. We initially reported the University of Pittsburgh experience with laparoscopic repair of 203 consecutive GPEHs. Median follow-up was 18 months. The most common preoperative
Chapter 35: Repair of Paraesophageal Hernia

Symptoms include heartburn (47%), dysphagia (35%), epigastric pain (26%), and vomiting (23%). Laparoscopic procedures performed included 69 Nissens, 112 Collis–Nissens, and 19 other procedures. Only three patients were converted to an open procedure, all nonurgently secondary to adhesions. Median length of stay was 3 days. Complications (minor or major) occurred in 57 of 203 patients (28%). There were six postoperative esophageal leaks (3%) and only one death. Five patients (2.5%) required reoperation for recurrent hiatal hernia. Good to excellent results were obtained in 92% of patients based on a postoperative questionnaire. The mean postoperative Gastroesophageal Reflux Disease Health-Related Quality-of-Life (GERD-HRQoL) score was 2.4 (scale 0 to 45; 0 = no symptoms, 45 = worst).

More recently, we published our results of laparoscopic repair of GPEH in 662 patients over a 12-year period, and this represents the largest series published to date (Luketich et al). The median patient age was 70 years, with a median percentage of herniated stomach of 70%. In this series, a Collis gastroplasty was performed in 63% of patients. The operative mortality was 1.7%. Postoperative GERD-HRQoL scores were available for 489 patients (30-month median follow-up), with good to excellent results in 90% (438/489). Reoperation was required in 3.2%, which is comparable to results reported in series where laparotomy or thoracotomy was performed.

In another study, we evaluated the long-term outcomes after laparoscopic repair of GPEHs in a subset of 187 patients, with a median clinical follow-up of 77 months. We evaluated clinical outcomes, barium esophagram, and QoL measures. A Collis gastroplasty was performed in a majority of patients (86%). A barium esophagram obtained in 82% of patients, demonstrated a radiographic recurrence in 15% of patients, though many recurrences were small and asymptomatic. A total of seven reoperations (4%) were required for symptomatic recurrence. The GERD-HRQoL scores were excellent to good in 87%. These results evaluating long-term follow-up show that there is a high degree of satisfaction among patients, and the rates of reoperation for symptomatic recurrence are low after laparoscopic repair in centers with extensive experience with open and minimally invasive esophageal surgery.

As the experience with antireflux surgery in the setting of GPEH has increased, we have come to recognize the important role of esophageal shortening in this condition. As described earlier, 75% to 90% of patients with true GPEH will have a GE junction located well above the diaphragmatic hiatus, and it is important to evaluate for a short esophagus. The proper assessment of esophageal length can be tricky because there is a tendency to overestimate the intra-abdominal length of the esophagus because of the diaphragmatic elevation caused by the pneumoperitoneum during the laparoscopy as well as the downward traction that is applied to the stomach. In addition, we have also gained experience with extensive mediastinal mobilization of the esophagus, when required. Once a short esophagus is recognized, complete mobilization of the esophagus in the mediastinum is important, prior to deciding whether to perform a Collis gastroplasty. We have found that with more extensive experience, and better mobilization of the esophagus, the need for a Collis gastroplasty may be reduced. An esophageal lengthening procedure should, however, be strongly considered in
the presence of a short esophagus despite adequate mediastinal mobilization.

In addition to an esophageal lengthening procedure, proper reconstruction of the hiatal defect is also critical to the long-term success of the repair. It is critical to preserve the crural integrity, while fully mobilizing the crura. In our experience, in the majority of patients the crura can be approximated primarily without undue tension, and we rarely have used mesh as an adjunct to the repair. In a review of the literature, the radiographic recurrence rate has been reported to be higher following a laparoscopic approach, ranging from 23% to 42%, depending on the duration of follow-up. Crural breakdown and wrap migration have been implicated in up to two-thirds of these failures. Failure rates are particularly prominent when the hiatal defect exceeds 5 cm since the crura may be quite attenuated and may not hold sutures well. Despite complete mobilization of the sac and crura, if the crura cannot be reapproximated without tension, the induced pneumothorax described above may allow a viable, good integrity diaphragm to be approximated without tension. If this is absolutely not possible, the surgeon has several options. Synthetic mesh has the propensity to erode into the esophagus. Thus, we try to avoid synthetic mesh if at all possible in this location, but there will be rare occasions when this may be considered to avoid leaving an obvious large defect. Some surgeons have described the use of a relaxing incision in the diaphragm that reduces the tension at the level of the hiatus. The relaxing incision is then closed with a polytetrafluoroethylene patch. Another approach, advocated by some authors, is bioprosthetic mesh cruroplasty. Biological mesh may be used to buttress the crural muscle so that sutures do not tear through or to actually serve as a patch to achieve closure of the hiatus.

In one randomized study evaluating mesh versus no mesh in laparoscopic repair of paraesophageal hernia, the early results favored placement of mesh; however, the long-term results showed no significant difference in the rate of recurrent hernia (Oelschlager). In this randomized study, primary diaphragm repair (PR) was compared with primary repair buttressed with a biologic prosthesis (small intestinal submucosa [SIS]). With early follow-up, the rate of radiologic hiatal hernia recurrence was higher with PR (24%) than with SIS buttressed repair (9%) after 6 months. The long-term results were recently reported. At a median follow-up of 58 months, there was significant recurrence of the hernia (>50%) in both the groups with 20 patients (59%) in the PR group and 14 patients (54%) with recurrent HH in the SIS group with no difference between the groups ($P = 0.7$). The repair of large paraesophageal hernia is a complex operation and there are several elements critical for the successful repair of a GPEH. This randomized trial addresses one element, the crural repair, that shows a very high recurrence rate at long-term follow-up with or without the addition of mesh.

It is critically important that several important aspects of the repair in this complex operation be considered and addressed. These include complete dissection of the hernia sac and removal from the chest, complete reduction of the hernia contents into the abdomen, preservation of the vagi, dissection of the GE fat pad and determination of the location of the GE junction, evaluation of intra-abdominal esophageal length, extensive mediastinal mobilization of the esophagus, the addition of a Collis gastroplasty if there is a short esophagus despite mediastinal mobilization, proper construction of the fundoplication, preservation of crural integrity, mobilization of the crura and a tension-free crural repair, and the use of a buttress in selected circumstances when a tension-free repair is not possible.

**RESULTS OF TRANSTHORACIC REPAIR**

The results of transthoracic repair of paraesophageal hernia with thoracotomy is well described with classical series of Pearson, Orringer, and Skinner. In the classic paper of Pearson (Maziak, et al.), the results of 94 patients with GPEHs repaired with an open approach were described. The preoperative symptoms included postprandial pain, dysphagia, iron deficiency anemia, and a history of symptomatic reflux. An open transthoracic approach was used in 97% of patients. A Belsey Mark IV repair was performed and a Collis gastroplasty was added in 80% of patients ($n = 75$) due to a short esophagus. The mean follow-up in this cohort of patients was 94 months and represents one of the longest reported in the literature. Good to excellent results were obtained in 93% of patients, and fair results were obtained in 4%. Two patients had a poor result, and both required reoperation with the addition of gastroplasty for a short esophagus.

In another series (Patel et al.), the results in 240 patients who underwent primary transthoracic repair of paraesophageal hiatal hernia were reported. Presenting complaints included reflux (69%), pain (67%), dysphagia (36%), and bleeding or anemia (33%). Preoperative esophageal function testing showed abnormal reflux in 86%. Hernia types were combined (type III) in 92% and type IV in 8%. All patients had reduction of the hernia and a Nissen fundoplication; an esophageal lengthening
Collins gastroplasty was performed in 96% of patients. The perioperative mortality was 1.7%. The mean follow-up in 226 patients was 42 months (median 27.8 months). Satisfactory results were obtained in 86% of patients. Of 19 patients with an anatomic recurrence, 4 (2%) had required reoperation. Postoperative esophageal function testing, obtained in 28% of the patients, showed normal GE reflux in two. The authors concluded that an open transthoracic repair of paraesophageal hiatal hernia provides good to excellent long-term control of both the hernia and GE reflux with relatively low early morbidity.

Some authors have questioned the need for a Collins gastroplasty, in light of the extensive transthoracic mobilization of the esophagus that is possible during thoracotomy. In another series (Altorki, Skinner), 47 patients with GPEH underwent transthoracic repair (n = 46) with reduction of the hernia and an antireflux procedure (Belsey in 28; Nissen in 19) without a Collins gastroplasty. The thoracic esophagus was extensively mobilized to the level of the aortic arch. An excellent to good result was reported in 90% of patients at a median follow-up of 45 months.

CONCLUSIONS

In summary, the repair of large paraesophageal hernia is a complex operation with several elements that are critical to achieving a successful repair. As shown by Pearson and colleagues and others, the transthoracic approach with a thoracotomy is a well-established technique for the repair of these hernia but increasingly the laparoscopic repair of GPEH is being utilized and is feasible, safe, and with lower morbidity, in centers with extensive experience in open and minimally invasive esophageal surgery. This has become the authors’ preferred approach.

The laparoscopic approach should adhere to the principles established during open operations: these include complete dissection of the hernia sac and removal from the chest, reduction of the stomach and herniated intra-abdominal contents to the abdomen, preservation of the vagi, dissection of the GE fat pad and determination of the location of the GE junction, careful assessment for esophageal shortening, the appropriate use of the Collins gastroplasty in patients with a short esophagus despite extensive mobilization of the esophagus, proper construction of the fundoplication, preservation of the integrity of the crura, mobilization of the crura and a tension-free crural repair, and the use of a buttress in selected circumstances when a tension-free repair is not possible. All these components of the operation are important and careful attention to all these elements of repair may reduce the incidence of recurrent herniation and improve long-term functional results.

SUGGESTED READINGS

Recognizing the low probability of an asymptomatic hernia causing problems the question as to whether to electively repair these remains an open one. One can make the case for continued observation while recognizing the very high potential mortality if strangulation should occur. The argument for elective repair of the asymptomatic patient becomes much more compelling if the operation can be done via the laparoscopic approach that the authors advocate. The caveat, however, is that these are complex procedures and should likely be done only by the most experienced laparoscopic surgeons who have significant experience repairing these hernias via an open procedure. It is imperative that strict attention be paid to the technical details spelled out by the authors if a high success rate for these procedures is to be achieved.

The authors make a convincing argument for the addition of an antireflux procedure to accompany the hernia repair, noting that it is likely that the appropriate dissection significantly disrupts the LES mechanism. The type of fundoplication should be determined based both on the surgeon’s experience but perhaps more importantly on the preoperative physiologic findings and should be individualized.

It seems that a significant factor involved in recurrence following hernia repair is the failed recognition of a fore-shortened esophagus. Recognizing that the assessment of esophageal shortening is difficult at the time of operation, there should be a low threshold to perform a Collins-type gastroplasty if there is any tendency for the reduced viscera to migrate back into the chest. It is likely that the

(continued)
majority of patients, especially those with chronic reflux symptoms, have a shortened esophagus and it is probably a good practice to err on the side of performing a gastroplasty though recognizing the possibility of slightly greater morbidity. The potential for a slightly higher incidence of morbidity needs to be weighed against the higher likelihood of recurrence. Once again the experience of the surgeon is key here in making this assessment.

With laparoscopy having become such an integral part of general surgery and of surgical training, it is probably safe to say that the thoracic approach to these lesions, and especially the Belsey-type repair done through the chest, is rarely done and likely will disappear altogether. Very few thoracic training programs provide enough experience with this procedure and the thoracic trainees all come with significant laparoscopic experience. It is highly likely that the Belsey Mark IV repair will be of historical interest only if that is not already the case (with apologies to Griff Pearson and the late Mr. Belsey).

LRK
INTRODUCTION
The incidence of technical complications associated with the use of cardiopulmonary bypass (CPB) has decreased greatly over the years, aided by the standardization of the equipment and techniques. The standardization of cannulation, cannulae, heart-lung machine, and myocardial protection has resulted in fewer iatrogenic complications such as aortic dissection, air embolism, or end-organ malperfusion. The use of such a standardized protocol is especially important for surgeons learning to use CPB, as well as for the other members of the operative team (anesthesiologists, nurses, and perfusionists), who will anticipate and prepare for each “next step” in the lengthy sequence of important steps in each operative procedure. The omission of one step (e.g., forgetting to give the heparin or forgetting to de-air the heart) can have devastating results in an otherwise well-performed operation. To facilitate the implementation of a standard protocol, all anesthesiologists, surgeons, and perfusionists should agree to standardization of their respective parts of the operation.

It goes without saying that surgeons-in-training should understand the perfusion circuitry, the priming solutions, maximum and minimum flow rates, safe levels of hemodilution during CPB, and the technical details of the system of myocardial protection being used. There should be an understanding of the chain of command, an appreciation of the areas of responsibility of each team member, and the need for open and concise communication among all team members during the course of the operative procedure.

Prior to going to the operating room the surgeon should have a plan for the operation, the expected pathology to be encountered, the type of incision best suited for this operation, the cannulation technique, the level of hypothermia, and the details of the myocardial protection to be used.

DEVELOPING A PLAN
Before each operation the surgeon must develop a plan for conducting the operation, especially the use and style of CPB. Although it is unnecessary for the anesthesiologist and perfusionists to know every technical detail of the planned procedure, it is critical that they understand the planned incisions, method of cannulating the heart and great vessels, the systemic and myocardial temperatures desired, the possible need for low flow or circulatory arrest, and any anticipated pathologic or anatomic variations that may require alterations in the plan of the procedure. It is advantageous for the surgeon to “think through” the entire operation before arriving in the operating room. This intellectual exercise begins by considering the critical elements of the planned operative procedure, which will determine the anatomic exposure required. For example, repair or replacement of the mitral valve requires maximum exposure of the right lateral aspect of the heart and the interatrial groove. Although neither the ventricles nor the left side of the heart need to be elevated, they must be able to be displaced into the left side of the pericardial cavity, or into the left pleural cavity. On the other hand, aortic valve replacement can usually be performed with simple aortic and right atrial cannulation “in situ,” and minimal manipulation or displacement of the ventricles. In general, coronary artery bypass grafting (CABG) requires exposure of all surfaces of the ventricles. Adequate exposure for the planned operation will be achieved by “suspending” or elevating the edges of the pericardium to make the relevant parts of the heart closer to the surface of the mediastinum, such that cannulation for CPB is easier, and the areas of the heart to be incised are closer to the surface. The operative plan will include the procedural steps of the operation, the technical details of the planned myocardial protection, and an estimate of the myocardial systemic temperatures required for the specific operation.

EXPOSURE OF THE HEART
For CABG the best exposure of the heart is via a median sternotomy. For aortic valve procedures, either a full sternotomy or an upper hemisternotomy can be used. The full sternotomy makes it easier to insert a left ventricular (LV) vent through the right superior pulmonary vein, and to insert the retrograde cardioplegia cannula via the right atrium into the coronary sinus. A young surgeon should use the full sternotomy for all aortic valve procedures until he or she feels comfortable using the smaller “mini-valve” incision. Mitral valve operations require a different exposure. A large left atrium, as in long-standing mitral stenosis or mitral regurgitation, is easily approached by decompressing the heart using a vent and excellent venous drainage, using superior and inferior caval cannulae, and retrograde and antegrade cardioplegia. A vertical incision in the left atrium close to the interatrial groove is made, and using a mitral valve retractor the surgeon has a great view of the mitral valve. When the left atrium is small, as in acute bacterial endocarditis or severe mitral regurgitation following acute myocardial infarction, it

36 Cardiopulmonary Bypass
Ivan K. Crosby and Richard K. Zacour
may be necessary to use caval snare, enter the right atrium, and incise the interatrial septum to expose the mitral valve. Again, although the surgeon might anticipate a “standard” valve or CABG procedure, he or she must always prepare for the unexpected: the valve that is irreparable, the infected aortic valve with a root abscess; the CABG patient with a shortage of suitable conduits; or the left internal mammary that is damaged during take-down, can it be salvaged and be a quality graft for the left anterior descending?meticulous attention to technical details should prevent such calamitous iatrogenic problems such as sternal saw injuries to the right ventricle, ascending aorta or innominate artery, or unrecognized “sheathing” of the aortic canulla in the wall of the ascending aorta, causing fatal total aortic dissection. The time-honored adage “chance favors the prepared mind” is very appropriate for all surgeons performing cardiac surgery.

The careful communication between perfusionists, anesthesiologist, surgeon, and nurse is essential in preventing and dealing with crises during the operation.

PREPARATION
A member of the surgical team should be present in the operating room as soon as the patient arrives. The anesthesiologist and associates are responsible for the induction of anesthesia, endotracheal intubation, as well as placement of most monitoring devices. The induction of anesthesia should not commence until good intravenous lines have been inserted and stable EKG monitoring established. If a patient is hemodynamically unstable an arterial line and pulmonary artery catheter should be inserted prior to the induction of anesthesia.

Positioning the Patient
After the insertion of all monitoring lines and the administration of anesthesia, the patient is positioned for the appropriate surgical incisions. All pressure points are padded to prevent pressure necrosis of the skin or nerve damage. All monitoring cables, infusion lines, and EKG cables are secured to prevent displacement or disconnection during the operation. Most cardiac surgical procedures utilize a median sternotomy. This is best done when the sternum of the patient is parallel to the operating room floor. This is achieved by placing a padded roll transversely beneath the patient’s shoulders and a padded ring placed under the head. In coronary revascularization procedures both legs should be “frogged” to facilitate harvest of the saphenous vein conduits. If a radial artery graft is planned, the left arm should be on an arm board abducted from the left side of the table. When a submammary right thoracotomy is planned the right chest is elevated 30 degrees on a “bump” under the right scapula and another one is placed under the right hip. The patient’s right arm is at the side on the table.

Skin Preparation and Draping
After the anesthetized patient has been properly positioned, a protective screen is placed at the head of the table just superior to the manubrium of the patient. This serves two purposes: (a) it supports the weight of the sterile drapes; (b) it separates the anesthesia team from the sterile field. It is important that the framework of this “ether screen”—traditional name for it—allows easy access to the endotracheal tube and neck lines by the anesthesia team. Antibacterial skin preparation needs to commence prior to the patient’s arrival in the operating room. For at least 1 day prior to surgery the patient should have one or more showers and hair wash with chlorhexidine, and gentle scrubbing of the chest, abdomen, and groins with a soft foam scrubber. After positioning in the operating room, the lower neck, chest, abdomen, both groins, and for multivessel coronary revascularization procedures, both lower extremities are painted with a two-solution antibacterial skin prep. When the skin is dry an antibacterial adhesive plastic drape is applied covering all the areas that need to be accessible for surgical incisions. The rest of the traditional sterile drapes complete the draping of the patient.

For every open-heart operation it is important to prep and drape both groins to facilitate rapid institution of CPB before the sternum is opened, should it become necessary, or to permit insertion of femoral arterial monitoring lines or an intra-aortic balloon pump.

The height of the operating room table is usually a compromise between the height desired by the surgeon and that desired by the first assistant. Some surgeons feel that the table height is optimal when the surgeon’s wrists are 1-3 cm below the elbow height when operating. The assistants adjust their position and elevation to accommodate the surgeon. The operating room lights are positioned initially to give the best exposure for the sternotomy incision. Subsequent adjustments are made to illuminate the appropriate area of the heart being treated. For mitral valve operations one light is positioned behind the surgeon, midway between the head and right shoulder such that it shines directly on the mitral valve.

The heart-lung machine and cell-saving equipment are brought into position and the pump lines and suckers are passed off the field to the perfusionists and circulating nurse. The pump lines are secured to the drapes on the side of the table near the patient’s right hip in such a way that the operative field is not compromised and the surgeons are unhampered. The lines should be secured to the drapes such that even excessive force cannot displace them. Inexperienced members of the team are instructed not to touch or compress the lines.

Incisions
The most common incision for cardiac surgical procedures is the median sternotomy. The length of the incision requires consideration of safety, effective exposure of the appropriate parts of the heart and, cosmetics. Anatomic and pathologic variations require careful planning to avoid disaster. A large ascending aortic aneurysm pressing against the back of the sternum, severe pectus excavatum, a patent internal mammary graft, or a redo operation all require the sternotomy incision to be performed with great caution. The length of the sternotomy incision can be shortened for cosmetic reasons. The superior extent of the skin incision might be midway between the top of the manubrium and the manubriosternal junction. Inferiorly, the incision can be stopped at the superior aspect of the xiphistemum. Experienced surgeons will elevate the skin of the inferior margin of the sternotomy incision and divide the xiphisternum process longitudinally along with the superior aspect of the linea alba, to allow effective exposure of the heart, but limiting the length of the skin incision. It is important for less-experienced surgeons not to compromise safety for cosmetics. When the sternal edges are spread using the sternal retractor the anterior aspect of the pericardium is clearly visible. The anterior layer of the pericardium is grasped with hemostats and the pericardium is incised from the acute angle of the heart inferiorty up to the pericardial reflection on the ascending aorta.

There are two basic techniques for elevating the heart closer to the sternal surface to facilitate exposure of the cardiac structures. One approach utilizes #1 silk traction sutures where the pericardium is stitched to the fascia at the edge of the sternal incision, or to the retractor itself. In the second technique two Kocher clamps grasp each side of the incised pericardium, the sternal retractor is loosened, and the edges of the pericardium in the Kocher
clamps are pulled up between the blades of the sternal retractor and the sternal edge. As the retractor is opened further the whole heart is elevated anteriorly giving excellent exposure. Caution should be used in spreading the sternal retractor too wide, as this can cause traction on the brachial plexus causing pain and numbness in the fourth and fifth fingers of the left hand postoperatively, or acute hypotension. If the length of the sternotomy skin incision is limited inferiorly, the pericardial incision should be carried down onto the diaphragm to give better exposure.

**Heparin**

Once the aortic and atrial pursestring sutures are in place, heparin should be administered. In some centers the heparin is given by the anesthesiologist into a central line. In other centers the surgeon will inject the heparin directly into the right atrial appendage so that there is no doubt that all the heparin is circulating. The normal heparinizing dose is 300 units/kg of patient bodyweight (Table 36.1). Additionally, 4 U porcine heparin/ml of pump prime is injected directly into the CPB circuit. However, heparin activity is patient specific and may vary if underlying coagulation defects are present. Confirmation of systemic anticoagulation is achieved by performing an activated clotting time (ACT). An uncontaminated whole blood sample is sent for ACT measurement 3 to 5 min after heparin injection for an activated clotting time (ACT) measurement.

The ACT must be >2.5 times the baseline ACT before initiating cardiopulmonary bypass, and must be maintained at >480 seconds during cardiopulmonary bypass.

The ACT should be monitored every 20 min during normothermic cardiopulmonary bypass, every 30 min during hypothermic cardiopulmonary bypass, and more frequently if the patient shows heparin resistance.

**Heparin Substitute**

In situations where heparin cannot be used we go to bivalirudin (Angiomax). Our protocol is as follows:

1. 50 mg in pump prime
2. 1 mg/kg bolus 20 minutes prior to CPB
3. 2.5 mg/kg/h continuous infusion following initial bolus
4. 0.1 to 0.5 mg/kg bolus to maintain desirable ACT of 500 seconds
5. Check ACT every 10 minutes while on bypass
6. Discontinue bivalirudin following termination of CPB
7. DO NOT use blood cardioplegia. Use crystalloid cardioplegia (Plegisol)
8. Flush CPB circuit with clear prime fluid into cell-saver once terminated

**Cannulation**

All cannulation pursestring sutures MUST be inserted before the heparin is given (Fig. 36.1). The full heparin dose must be given and have circulated BEFORE any cannulae are inserted. In its simplest form CPB requires a cannula in the ascending aorta and a cannula in the right side of the heart. The type of procedure to be performed will dictate where the cannula is placed in the ascending aorta and what type of cannulation is performed on the right side of the heart. If a coronary bypass procedure is being performed, the cannula in the ascending aorta will be placed close to the innominate artery or even in the arch area. This will allow a large area of the ascending aorta for the placement of proximal graft anastomoses.

**Anticoagulation Management Protocol**

Add 4 U of beef lung heparin per milliliter of the pump prime to the cardiopulmonary bypass circuit.

The surgeon injects 300 U of beef lung heparin per kilogram of patient body weight into the right atrium.

An uncontaminated whole blood sample is drawn 3–5 min after heparin injection for an activated clotting time (ACT) measurement.

The ACT must be >2.5 times the baseline ACT before initiating cardiopulmonary bypass, and must be maintained at >480 seconds during cardiopulmonary bypass.

The ACT should be monitored every 20 min during normothermic cardiopulmonary bypass, every 30 min during hypothermic cardiopulmonary bypass, and more frequently if the patient shows heparin resistance.

professors. Before any aortic pursestrings are inserted, however, the surgeon should perform gentle digital evaluation of the entire ascending aorta, innominate artery, and aortic arch. In choosing a cannulation site he or she needs to avoid areas of calcification or atherosclerosis in the aorta. If there is any question, the aorta should be evaluated with an epiaortic probe. Of prime importance is the need for the cannula tip to lie in the lumen of the aorta (Fig. 36.2), not against or penetrating the wall of the aorta (“sheathing” the cannula, causing a type A aortic dissection). Also it should not be inserted so far that the tip of the cannula goes up the innominate artery or the left carotid artery. The jet from the cannula tip should not act like a “fire hose” directed at atherosclerotic plaque and shower emboli to the brain. Many surgeons prefer that the length of the cannula that penetrates the aortic wall should be no more than 2 to 3 cm (Fig. 36.2). Although some surgeons prefer a much longer cannula penetration into the aorta such that the tip of the cannula lies in the distal aortic arch, avoiding the innominate, the left carotid, and the left subclavian artery orifices, we feel that it is hard for trainee surgeons to be sure that the tip placement is perfect using this latter technique. The aortic pursestring is usually a 3-0 monofilament or braided suture. The diameter of the pursestring is usually 1 to 1/3 times the diameter of the aortic cannula being used. There is usually an inner pursestring and an outer pursestring and some surgeons prefer to use pledgets with these pursestrings (Figs. 36.3, 36.4, 36.5). The needle bites of the double-armed sutures should penetrate the adventitia and into the media of the aortic wall, but not into the lumen of the aorta. After completing the pursestrings, the needles are removed and both ends of the suture drawn through a tourniquet or snare. There are thus two tourniquets to secure the aortic cannula when it is inserted.

There are three commonly used techniques for inserting the aortic cannula in the aorta:

(a) Using a #11 blade, and taking care not to cut the pursestring sutures, the surgeon makes a stab incision through the aortic wall inside the pursestrings circle (Fig. 36.5). Removing the blade, the left index finger quickly tamponades the incision to prevent hemorrhage.

(b) Some surgeons prefer to use a #15 blade and make a vertical incision within the pursestrings, layer by layer of the aorta, until only the intimal layer remains. Holding the preadjusted cannula in the right hand the cannula is carefully pushed through the intima into the lumen of the aorta. The aortic cannula is desired as above and secured (Fig. 36.2).

(c) Ambidextrous surgeons can make the incision into the aorta inside the pursestring circle with the left hand using a #15 blade, and keeping the body of the #15 blade inside the aorta, they hold the cannula in their right hand and slide the tip of the cannula off the #15 blade into the aortic lumen (a “shoe-horn” maneuver). The cannula is then secured and deaired as above. No matter which technique is used to insert the aortic cannula into the aorta, the surgeon must meticulously remove all air and debris from the cannula as it is connected to the arterial line from the heart–lung machine, and the clamp is removed from the aortic cannula.

The “bumper” on the aortic cannula has already been adjusted to limit the depth of penetration of the cannula into the aorta. As the left index finger moves from the stab incision in the aorta the right hand gently but quickly pushes the aortic cannula into the aortic lumen. The sternal or tourniquets are tightened down and then tied to the cannula above the bumper to prevent the cannula from backing out of the aorta. The clamp on the aortic cannula is briefly released to remove all air from the cannula and the clamp reapplied (Fig. 36.2).

Alternative Cannulation Sites

Arterial cannulation of the distal ascending aorta or aortic arch may not be desirable or possible if there is extensive calcification of the entire ascending aorta and arch, or if there is an acute aortic dissection involving the ascending aorta and arch (type A), or a large aneurysm involving the arch. In such circumstances there are two alternative cannulation sites to consider: the right axillary artery or the femoral artery.

The right axillary is exposed using a small subclavicular incision. The pectoralis muscle is split or divided, exposing the axillary artery. Gentle mobilization is necessary to avoid injury to the adjacent brachial plexus, or causing spasm of the axillary artery itself. After heparinization of the patient a segment of the artery is isolated.

Fig. 36.2. The final position of the aortic cannula in an adult.
between gentle vascular clamps, and an 8 mm longitudinal incision is made on the anterior aspect of the artery. A 10 cm length of 8 mm diameter prosthetic graft is sewn end-to-side to the 8 mm arteriotomy using a 5-0 polypropylene running suture. The arterial cannula is inserted into this graft and secured with a heavy silk suture ligature.

The tip of the arterial cannula should be 2 to 3 cm from the axillary artery. After the CPB is discontinued and the patient is quite stable, the cannula is removed and the prosthetic graft is transected, leaving a 5 mm cuff which is oversewn with a running 5-0 suture.

Femoral cannulation is not desirable if the patient has aortoiliac occlusive disease with severely diminished or absent femoral pulses. When used it requires a short vertical skin incision directly over the common femoral artery. Using electrocautery for hemostasis, the common, superficial, and profunda arteries are encircled for control. An umbilical tape is passed around the common, and the ends drawn through a tourniquet. With the patient fully heparinized, the distal vessels are occluded, a vascular clamp occludes the common femoral, and a transverse arteriotomy is made in a soft part of the common femoral on its anterior surface, not longer than 50% of the circumference of the artery. The arterial (femoral) cannula is advanced proximally up the common femoral artery and the umbilical tape tourniquet is tightened just enough for hemostasis, and is then secured to the cannula with a heavy silk ligature. On completion of CPB the cannula is removed, and the arteriotomy closed with a continuous 5-0 suture.

Percutaneous femoral cannulation can be performed as an alternative to open exposure of the femoral artery or vein (or both) using the Seldinger technique.

Atrial Cannulation
When the right atrium is opened for repair of septal defects or tricuspid valve surgery two venous cannulae will be placed—one in the superior vena cava (SVC) and the second in the inferior vena cava (IVC) (Figs. 36.6 and 36.7). Caval “snares” or tourniquets are then placed around the superior and inferior cavae, such that when the tourniquets are tightened around the superior and inferior caval cannulae, the patient is then on “total” CPB, and the right atrium can be opened with a dry operative field. When mitral valve procedures are being performed, two venous cannulae are frequently used to facilitate exposure of the mitral valve. The mitral valve retractor must not compromise the venous return. For many cardiac operations, such as aortic valve replacement or coronary bypass surgery, a “two-stage” single venous cannula is inserted via the right atrial appendage (Fig. 36.8).

Bicaval Cannulation
When two caval cannulae are used to facilitate the venous drainage of the heart, a
As the tubing clamp near the top of the cannula is released briefly, the surgeon’s right hand presses on the right upper quadrant of the patient’s abdomen to fill the cannula with blood, the tubing clamp is reapplied, and the venous cannula connected to the venous return line to the heart–lung machine. Insertion of the superior caval cannula is often done by placing a vascular clamp across the base of the atrial appendage that is encircled by the superior pursestring. The tip of the appendage is amputated, and as the vascular clamp is removed, the superior caval cannula enters the right atrium, is advanced into the SVC, and secured with the tourniquet. Connection of the two caval cannulae to the venous return line is accomplished in a meticulous way. Both venous cannulae should be filled with blood. A bulb syringe filled with saline fills the connector on the venous line and the venous line itself with saline. Both caval cannulae are then connected to the venous line Y-connector. The tubing clamps are then reapplied keeping air out of the heart (Figs. 36.6 and 36.7).

Two-Stage Venous Cannula

The two-stage venous cannula, with or without suction, provides excellent

Section II: Adult Cardiac Surgery

Retrograde Cardioplegia Cannula

Before the heparin is administered, a 4-0 polypropylene pursestring suture is placed in the ascending aorta above the aortic valve but proximal to where the aortic cross clamp will be applied (Fig. 36.1). In CABG procedures this cannula is positioned such that this cannulation site in the aorta is used for one of the proximal anastomoses. This allows insertion of the antegrade cardioplegia/aortic vent cannula into the aorta. When the cannula is back flushed and filled with blood the cardioplegia line is connected, while a vent suction line is connected to the other tube of the cardioplegia/vent cannula, which is then occluded.

Indications for Left Ventricular Venting

Venting of the left side of the heart is most important in different circumstances:

(a) Severe aortic valve regurgitation. The institution of CPB in a patient with severe aortic valvular insufficiency causes immediate LV distension. Unless this is corrected immediately (by cross clamping the aorta and venting the LV), it will result in severe damage to the LV.

(b) Antegrade cardioplegia. If there is any degree of aortic valve regurgitation when antegrade cardioplegia is being administered, the LV will become distended with cardioplegia. To prevent damage to LV function the LV needs to be vented.

(c) Incomplete drainage of the venous return. If there is inadequate drainage of the right side of the heart or kinking/obstruction of the venous return line, both sides of the heart will become distended. If severe, this can cause a dramatic fall-off in cardiac contractility. An LV vent can obviate this problem, together with improved drainage of the right side of the heart.

(d) Evacuation of air from the heart. For such operations as aortic valve replacement, mitral valve repair or replacement, LV aneurysmectomy, atrial or ventricular septal defect procedures, after completion of the definitive procedure, a considerable amount of air will be present in the left atrium and LV. While the heart is arrested and motionless this is not a problem. However, unless all this air is evacuated before the heart starts beating, there is a serious risk that some of this air will be pumped from the heart into the arterial circulation. This can cause cerebral obtundation or stroke, air down the coronary arteries resulting in infarction or LV power failure, end organ or peripheral ischemia.

To prevent air embolism most surgeons use a LV vent and an aortic vent. The LV is decompressed using a catheter inserted through the right superior pulmonary vein (Fig. 36.1) and advanced into the LV chamber. Air is evacuated from the ascending aorta using the antegrade cardioplegia/aortic vent cannula.
cut edges of the aorta together to prevent bleeding. When the surgeon is ready, the forceps are parted, and the aorta is raised to give counter pressure as the surgeon inserts the cannula, entering the aorta at a right angle to the direction of blood flow and tilting the external cannula inferiorly as he or she advances it the equivalent of 1 to 1/3 times the aortic diameter (Fig. 36.9). The position of the cannula is confirmed by palpation to be sure it has not entered the innominate artery and that the tip lies on the inner curve of the aortic arch just distal to the pericardial reflection. The pursestring suture is drawn tight in its tourniquet and secured to the cannula with a heavy ligature. After the aortic cannula has been de-aired and connected to the arterial pump line, it is secured to the drapes to avoid undue tension.

In infants and young children, venous cannulation is performed by modifying commercially available thin-walled, wire-wound cannulas. For double-caval cannulation, the unwired portion of the tip is trimmed to provide two proximal side holes and an oblique bevel. Insertion techniques are similar to those for adults, but often a right-angled cannula with a metal or plastic tip is inserted directly into the SVC, rather than into the right atrium.
when using two venous cannulae. When a single venous cannula is to be used in infants, it is modified to leave four side holes and is inserted through the right atrial appendage, so that only the tip lies in the orifice of the IVC to provide free drainage of the right atrium. In neonates a single 12F or 14F cannula is used.

**Left Ventricular Venting Technique**

If an LV vent is needed, it is inserted before commencing CPB. The anesthesiologist performs a Valsalva maneuver to elevate the left atrial pressure. An incision is made in the pursestring suture at the juncture of the right superior pulmonary vein and left atrium (Fig. 36.1), and the fluid-filled cannula is immediately inserted. The cannula should have a curve that forms nearly a right angle and should be aimed with its tip hugging the anterior atrial surface and directed toward the LV apex. Except in mitral stenosis, it will pass immediately into the LV in its appropriate position, which can be confirmed by signs of pulsatility within the cannula, or by the surgeon's hand palpating in the oblique sinus. If the vent cannula is stiff, caution must be used to limit the length of the cannula inserted through the pursestring into the heart, so that the tip of the stiff cannula does not puncture or perforate the apex of the LV.

Some surgeons prefer to insert the LV vent while on CPB. The perfusionist fills the heart by occluding the venous line, translocating blood volume from the bypass circuit to elevate the left atrial pressure. When the stab incision is made within the pursestring, blood under pressure flows from the left atrium (preventing the ingress of air into the left atrium), while the LV vent catheter is advanced into the LV.

**Cardiopulmonary Bypass Circuit**

The foremost principle of CPB management is to minimize the patient’s metabolic adaptation to a nonphysiologic state, a state of “controlled shock” and nonpulsatile perfusion. To accomplish this, the perfusionist must meticulously prepare the extracorporeal circuit and manage the dynamic characteristics of CPB (Fig. 36.10). The circuit design and the selection of the arterial and venous cannula are based on the calculated blood flow rates necessary to provide adequate hemodynamic support and gas exchange (Table 36.2). The cannula tip is the narrowest component of the extracorporeal circuit and creates an environment of high-resistance, high-pressure gradients and turbulence. The cannulae are described by either French size or in millimeters, which reflects only the external dimensions, without regard to the internal diameter or performance characteristics. Although flow characteristic and pressure drop can be calculated for straight tubing, cannula performance characteristics complicate these calculations due to varying lengths, the presence of side holes or curves, and irregular diameters. These factors, along with ratio of internal diameter to external diameter (ID/OD) need to be considered when selecting a cannula (Table 36.3). Performance characteristics and the pressure-flow relationship of any given cannula should be reviewed and a pressure gradient not exceeding 100 mmHg at “full flows” is recommended for an arterial cannula.

The performance characteristics of venous cannula are even more vital than those of the arterial cannula since blood flow through the extracorporeal circuit is dependent upon the venous return, which may be either passive or “assisted.” Passive venous return is the more traditional method of providing extracorporeal circulation, and is dependent upon gravity, the level of the heart above the venous reservoir (40 to 70 cm), and large-bore tubing.
“Assisted” venous return has been used in some centers in the United States for 5 to 6 years, and is achieved with the aid of vacuum being applied to the venous line or reservoir. Assisted venous return provides some advantages over the traditional venous drainage, such as permitting smaller-diameter venous lines and cannulae, smaller incisions, and lowering the extracorporeal circuit priming volume. However, potential disadvantages of assisted venous return include an increase in gaseous microemboli if the vacuum is too great, and the reservoir volume is too small to accommodate the expected gaseous microemboli from the blood, and an increase of hemolysis if the vacuum rate is too great. Because of these concerns, we prefer to maintain a negative pressure similar to gravity drainage, limit the amount of vacuum to less than −60 mmHg, and prefer to maintain a venous reservoir volume sufficient enough to provide a 10-second reaction time. Currently in the United States about 55% of heart surgery teams use passive venous return, and 45% of teams use assisted venous return. Regardless of the method utilized, venous return will be reduced if the side ports of an oversized venous cannula are obstructed by an overstretched cava, or if the internal diameter of the venous line and/or cannula is too small to accommodate the expected venous return. This results in overdistention of the right heart and/or flooding of the operative field. An appropriate venous cannula will have a pressure gradient of less than 30 mmHg at the rated blood flow, and will not allow an excessive negative pressure to develop (the ideal venous pressure should range between 0 to 5 mmHg). The patient’s size determines the design of the extracorporeal circuit and the priming volume. The blood volume of all patients, from pediatric to adult, can be calculated from Table 36.4. The degree of hemodilution may be calculated before bypass is initiated, and if the expected priming volume would cause an “unacceptable” anemia, occasionally packed red blood cells may be added to the extracorporeal circuit before commencing CPB (Tables 36.5 and 36.6).

Hemodilution provides an advantageous effect for perfusion by decreasing fluid viscosity and by augmenting blood flow. One deleterious side effect of hemodilution is the reduction of oncotic pressure, resulting in tissue edema. There is an inverse relationship between tissue edema and colloid oncotic pressure, and when albumin or mannitol is added to the extracorporeal circuit to obtain an oncotic pressure of 16 mmHg, extracellular fluid accumulation is reduced. Although blood flow reflects the interaction of many influences, hemo-dilution aids in negating those inherent effects by diminishing blood’s viscosity and resistance to flow, and promotes increased microcirculatory flow and tissue perfusion. Hypothermia also influences blood rheology and vascular geometry. A decrease in temperature provokes direct vasoconstriction and increases viscosity, creating sludging and stasis at the capillary level, resulting in reduced blood flow. These effects are counteracted by hemodilution. Is there an “acceptable” degree of hemodilution? It is common to see hematocrits of 18% to 21% during CPB, and even extreme hemodilutional hematocrits of <15% are well tolerated when used for circulatory arrest cases or for patients who are Jehovah’s Witnesses. A general rule of thumb is that the hematocrit in percent should not exceed the desired level of hypothermia in degrees Celsius. Currently our threshold for adding packed cells to the pump is a hematocrit of <18%.

We use a blood conservation strategy as follows:
1. A transfusion threshold at a hematocrit of less than 18% unless the patient has a history of cerebrovascular disease, carotid stenosis, or diabetes
2. The patient’s clinical condition mandates a transfusion trigger of 21% to 24% (advanced age, severity of illness, cardiac function, end-organ ischemia, massive or active blood loss)
3. Routine use of cell-saver, except in cases of infection and/or malignancy
4. Utilizing low-prime and mini-extracorporeal bypass circuits (Table 36.5).

extracorporeal circuit should be free flowing and exhibit a reasonable extracorporeal line pressure. A sudden spike in the extracorporeal line pressure may indicate an occluded arterial line, a malpositioned aortic cannula, or an aortic dissection. Should this occur, CPB is terminated immediately and the cause identified and corrected. As soon as it is obvious the arterial flow is unobstructed, the perfusionist releases the venous clamp, diverting the patient’s venous return blood into the CPB circuit (Fig. 36.10). The right heart should be decompressed and the central venous pressure should be <5 mmHg. A high central venous pressure and poor venous drainage at the initiation of CPB may indicate a malpositioned venous cannula, a kinked venous line, an “air lock,” venous cannulae that are too large or too small, an inappropriate height between the operating table and the venous reservoir, an inappropriate amount of vacuum, or a vacuum leak. During this transition period of 1 to 2 minutes, the perfusionist gradually increases the rate of arterial flow, the ventricles receive less blood, and the pulsatile arterial waveform diminishes and becomes “flat-lined.” Once total bypass is achieved, a continued pulsatile arterial waveform signifies the LV is receiving unwanted blood from aortic valvular insufficiency, excessive bronchial venous return, or incomplete drainage of the systemic venous return.

An acute, transient state of systemic arterial hypotension, resulting from hemodilution and vasoactive substance release, is common on the initiation of CPB. Treatment with alpha agonists is usually not necessary to overcome this acute state because the mean arterial pressure will generally increase with the initiation of systemic cooling (due to its induced vasoconstriction) and increased levels of endogenous catecholamines and angiotensin. The arterial pressure during total CPB is a mean or “flat-line” pressure, unless an artificial means is used to generate pulsatile flow. The mean pressure should be viewed as an index of the relationship between blood flow, volume, and arteriolar resistance, and not as a measure of perfusion adequacy.

The body surface area and weight of the patient determine the desired flow through the heart–lung machine while on CPB (Table 36.2). Although the subject of much debate, an “acceptable” mean arterial pressure ranges from 35 to 90 mmHg. However, in the presence of known coronary artery stenosis or ventricular hypertrophy, a perfusion pressure of 60 to 80 mmHg should be maintained. In patients with known carotid artery stenosis, we recommend keeping the perfusion pressure between 80 to 100 mmHg. In general, if the systemic vascular resistance index and mixed venous blood gases are normal, the resultant mean arterial pressure is “acceptable.” In patients with severe aortic regurgitation, the surgeon should be ready to cross-clamp the ascending aorta if the heart becomes distended or if ventricular fibrillation occurs. If the heart continues to beat, the left atrium should not be entered until the aorta has been cross-clamped to prevent embolization of air to the brain. In children and infants with congenital heart disease, the right heart should not be opened until the aorta is cross-clamped or ventricular fibrillation has occurred. However, decompression of the LV is best achieved in infants and small children by tightening the vena cava tapes, opening the right atrium, and passing a small suction line through the patent foramen ovale into the LV. If the foramen is not patent, a small stab wound will permit this approach.

Cooling the Patient
The perfusionist can begin cooling the perfusate to induce hypothermia once full flow and adequate decompression are established. The primary advantage of hypothermic CPB is the reduced metabolic rate and oxygen consumption; although not linear, this approximates 5% to 7% per degree Celsius that the body temperature is lowered. In addition, hypothermia sustains intracellular reservoirs of high-energy phosphates (essential for cellular integrity) and preserves high intracellular pH and electrolyte neutrality (a constant OH⁻/H⁺ ratio). As a result of these associated interactions, hypothermic patients can survive periods of circulatory arrest of up to 1 hour without suffering from the effects of anoxia (Table 36.7).

Hypothermia may be induced by surface cooling using cooling blankets and ice packs applied directly to the patient, or by core cooling with cold perfusate from the extracorporeal circuit. Because tissues and organs have varying blood flows, systemic cooling is not a uniform process. To minimize this, we combine the two methods, maintain high perfusion flow rates of 2.2 to 2.5 L/min/m², and limit the rate of the cooling to <1 degree Celsius/minute until the desired temperature is reached. Thereafter, perfusion flow rates are adjusted to maintain “normal” mixed venous blood gases. Bladder and nasopharyngeal temperatures are monitored to ensure uniform temperatures.

Rewarming
As the intracardiac procedure is being completed, systemic rewarming is instituted by gradually increasing the perfusate temperature. Rewarming is slower than cooling because of the maximum 10 degrees Celsius permissible temperature gradient between perfusate and nasopharyngeal temperatures, the maximum allowable blood temperature of 42 degrees Celsius, and the reduced thermal exchange as the temperature gradient between the patient and perfusate narrows. During this state, the warming blanket is set to 40 degrees Celsius, the perfusion flow rates are increased to 2.5 to 3.0 L/min/m² (Table 36.2), and pressure permitting, pharmacologic vasodilation is used. When the bladder temperature reaches 32 degrees Celsius, the patient begins to vasodilate spontaneously and the pharmacologic vasodilator may be terminated.

Removal of Air from the Heart
With the aorta cross-clamped, the patient is placed in a 30-degree head-down position, the caval tourniquets are loosened, and the perfusionist restricts venous return to the pump. The right heart begins to fill, and the anesthesiologist ventilates the lungs. The heart is gently massaged while the vent in the LV continues to drain. The antegrade cardioplegic cannula is placed on suction and, as more blood is massaged through the left heart, some air is removed via the antegrade cardioplegic cannula. Once all air appears to have been evacuated, the balloon of the

Discontinuing Cardiopulmonary Bypass

Especially if the patient had compromised ventricular function preoperatively, or had a lengthy or complex repair, termination of CPB is performed gradually, with constant communication between surgeon, perfusionist, and anesthesiologist. The surgeon will always check to be sure the LUNGS are being VENTILATED before weaning the patient from CPB. Because the heart cannot generate a cardiac output until the central blood volume is restored, the perfusionist progressively occludes the venous return line, translocating blood volume from the venous reservoir into the patient’s vascular system. The patient is now on “partial” CPB, with blood flowing through the heart and pulmonary circulation. When the blood volume in the heart reaches an adequate level, the aortic valve begins to open with each heartbeat, and a measurable cardiac output and arterial waveform will be observed with each cardiac contraction. The translocation of volume by the perfusionist is continued until the arterial systolic pressure reaches 100 mmHg. The perfusionist then terminates CPB by completely occluding the venous and arterial lines. Thereafter, the perfusionist transfuses volume to the patient to maintain a systolic blood pressure of 100 mmHg unless the heart becomes distended.

If the heart does not function effectively when CPB is terminated, bypass is re instituted to prevent overdistention of the LV or hypoxia, and inotropic support will be started. When good cardiac function and hemodynamic stability have been achieved, CPB is discontinued, and decannulation can begin. If two venous cannulas were used, the inferior caval cannula is removed, and the pursestring suture is tied. If two venous cannulas were used, the inferior caval cannula is removed, and the pursestring suture is tied. If two venous cannulas were used, the inferior caval cannula is removed, and the pursestring suture is tied. If two venous cannulas were used, the inferior caval cannula is removed, and the pursestring suture is tied. If two venous cannulas were used, the inferior caval cannula is removed, and the pursestring suture is tied.

Appropriate postoperative monitoring lines are inserted by the anesthesia team prior to the sternotomy and, if indicated, temporary pacing wires are sutured to the right ventricle and the right atrium. Rewarming is continued until the nasopharyngeal temperature is 37 degrees Celsius and the bladder temperature is >36 degrees Celsius.

This rewarming usually takes 3 to 5 minutes for each 1 degree Celsius increase.

Removal of the Arterial Cannula

In adult patients with two pursestring sutures, the tourniquets are slipped off the pursestring sutures. The surgeon holds the arterial line while the assistant places the first overhand throw in the pursestring suture on his or her side. The arterial cannula is removed, and the assistant’s pursestring is cinched down and held in position for hemostasis. The surgeon takes the pursestring on his or her side and ties this firmly. The assistant then completes tying the other pursestring suture. Once all protamine has been administered and the patient is stable, the pursestring suture on the right atrial appendage is tied and, if necessary, reinforced with a second suture. Thereafter, final hemostasis and surgical closure of the wound are performed according to protocol.

Sternal Closure

The pericardial cavity, and frequently the left pleural cavity (if the left chest has been opened with take-down of the mammary artery), is drained with two or three chest tubes. Our preference is for a flat tube to be placed under the right ventricle and into the posterior part of the pericardial cavity; a round Blake tube drains the anterior retrosternal space, and another Blake drain is placed in the left chest. These chest tubes are brought out through 10 to 12 mm incisions just below the bottom end of the sternotomy incision, on either side of it. The left chest tube can be brought out through an intercostal incision in the anterior axillary line just above the abdomen (draining the bottom of the left hemithorax), or through a small incision just lateral to the mediastinal tube incisions.

Closure of the sternum can be accomplished in a variety of ways. We favor a very secure closure, as if a patient sneezes; it is always very disappointing if he/she dehisces his/her sternotomy closure. Our skin incisions are closed with a subcuticular closure.

PUMP-ASSIST CORONARY ARTERY BYPASS GRAFTING

In off-pump CABG the coronary revascularization is usually performed without using CPB. However in a small percentage of cases the support of CPB makes the operation safer. If a patient has had a recent transmural myocardial infarct, or has an ejection fraction of 5% to 10% some surgeons use “pump assist.” Normothermic CPB is used without arresting the heart,
and the coronary bypasses performed in the usual off-pump way.

**FEMOROFEMORAL BYPASS**

Certain complex problems can be managed more safely using femorofemoral bypass, rather than traditional CPB. A mycotic aneurysm of the ascending aorta that is right up against the back of the sternum, and is bulging out over the top of the sternum would pose a major risk of massive hemorrhage with a standard sternotomy. Again, a redo CABG operation where there is a patent internal mammary graft in the retrosternal area, or a redo operation where the right ventricle is stuck to the posterior table of the sternum might also benefit from femorofemoral bypass. Finally, rapid rewarming of a patient who has undergone a hypothermic cardiac arrest can easily be achieved by this form of full CPB support. Again, this can be performed using percutaneous cannulation or open cannulation techniques. Especially if there is vacuum-assisted venous return, full CPB can be established using femorofemoral bypass, with core-cooling and rewarming.

**LEFT HEART BYPASS**

Patients with descending thoracic or large thoracoabdominal aortic aneurysms have a lower incidence of spinal cord complications if left heart bypass improves distal organ perfusion during the aortic repair. This support system is not truly CPB as there is no oxygenation of the blood, but simple pumping of oxygenated blood from the left atrium to the arterial vessels distal to the clamped-off aneurysm. For this type of bypass a cannula is passed through a pursestring suture in the left inferior pulmonary vein, and advanced into the left atrium. All air is removed by back-bleeding and then clamping the atrial cannula. The distal cannula is placed through two pursestrings in the distal thoracic aorta below the aneurysm, or into the femoral artery. During this left heart bypass the flows range from 1 to 3 L/min. After completion of the aneurysm repair the cannulae are removed and the pursestrings tied.

**BIG PICTURE**

Modern CPB, incorporating excellent drainage of the right side of the heart, antegrade and retrograde myocardial protection, aortic and if necessary LV venting, allows the performance of complex reconstructive procedures with great safety. However, it requires many technical procedural steps, and makes for a very busy operative field (Figs. 36.10 and 36.11).

**SUGGESTED READINGS**

![Fig. 36.11. Completed cannulation for total cardiopulmonary bypass. The left ventricular, venting catheter has been inserted via the right superior pulmonary vein. The retrograde cardioplegia catheter is in the coronary sinus. The antegrade cardioplegia catheter is in the ascending aorta proximal to the aortic occluding clamp. (IVC, inferior vena cava; LV, left ventricle; SVC, superior vena cava.)](image-url)
The authors of this chapter have done a very careful analysis of the basics of cardio-pulmonary bypass. They have emphasized familiarity with the devices, standardized protocols, and most importantly teamwork. Cardiac surgery is a team sport and this cannot be overemphasized. Discussions at the beginning of each surgery will certainly clarify any issues between the various groups involved in the care of these very important patients. I think the techniques for cannulation as well as the approaches to avoid the disasters that are inherently present in our specialty are very well done. I would like to emphasize the importance of the discussion on venous drainage particularly assisted venous drainage. Keeping the right heart empty markedly protects the heart by avoiding distention and induced fibrillation as blood enters the coronaries in a retrograde fashion. This is an area that I truly emphasize in my practice and it is well described in this chapter.

ILK
This chapter reviews current concepts regarding myocardial protection during cardiac procedures including minimally invasive procedures with or without robotic assistance. In addition, myocardial protection in orthotopic heart transplant will be discussed. We provide the rationale of our strategy and describe the methodology of our approach in detail.

The strategies available for myocardial protection have led to adversarial positions regarding warm versus cold blood cardioplegia, as well as antegrade versus retrograde delivery. This creates confusion and potentially deprives the patient of the benefits of each method. In principle, cardioplegia markedly reduces oxygen demand in the arrested heart and must be delivered in sufficient quantity to all regions to match myocardial demand (Fig. 37.1). This has led to our use of antegrade and adjunct retrograde delivery, cold methods to reduce the demands allowing bloodless visualization, and warm reperfusion for resuscitation.

Our “integrated method” is a strategy of myocardial protection that combines the advantages of different concepts, allowing the operation to be conducted without interruptions.

The principle goals of cardioplegia are:

1. Providing and maintaining electromechanical arrest of the myocardium.
2. Sustained cooling of the myocardium, while flushing out unwanted toxins and warm blood.
3. Limiting myocardial edema and providing buffering capacity.
4. Limiting ischemic and reperfusion injury to the myocardium.

Electromechanical activity during cardiac arrest raises oxygen demand during ischemia. Hypothermia is a crucial component of myocardial protection because it reduces myocardial oxygen demand (Fig. 37.1). Blood cardioplegia is now preferred by most surgeons because of its versatility. It maintains oncotic pressure, is a natural buffering agent, has advantageous rheologic properties, and is a free-radical scavenger. Blood cardioplegia also limits reperfusion injury and reverses ischemia/reperfusion changes in the acutely ischemic myocardium. These beneficial features may not be possible with crystalloid cardioplegia.

Noncardioplegia methods have been applied in special situations. For example, when a severely calcified aorta is encountered, the preferred technique is deep hypothermic arrest (approximately 20°C) without aortic clamping.

**COLD BLOOD CARDIOPLEgia**

Cold blood cardioplegia allows complete myocardial recovery after 4 hours of ischemia in normal hearts. Hypothermia lowers myocardial oxygen demand and ischemic damage when coronary flow is interrupted in the course of the revascularization procedure, provided the cardioplegic perfusate is distributed adequately with reinfusions. Hypothermia alone, however, does not avoid injury in chronically “energy-depleted” (ischemic) hearts (Fig. 37.2). Furthermore, hypothermic crystalloid cardioplegia adds some disadvantages, such as shifting the oxyhemoglobin association curve leftward, retarding Na⁺/K⁺ adenosine triphosphatase to produce edema activation of platelets, and creating free radicals. Blood cardioplegia consists of four parts of blood to one part of crystalloid solution. This limits the hemodilution seen with crystalloid cardioplegia during repeated infusions.

**WARM BLOOD CARDIOPLEgia**

Warm blood cardioplegia (37°C) given initially (induction) limits reperfusion damage in ischemic hearts. It enhances metabolic repair by channeling aerobic adenosine triphosphate production to reparative processes. Other cardioplegic components, citrate phosphate dextrose (CPD) and buffers (THAM [tromethamine; tris-hydroxymethylaminomethane]), limit calcium influx and acidosis. Clinical studies confirm experimental findings and show that warm blood cardioplegia (“hot shot”) after ischemia improves recovery. Warm cardioplegic induction and reperfusion solutions are augmented with the amino acids glutamate and aspartate to replenish key Krebs-cycle intermediates depleted by ischemia. These additions enhance the reparative processes after a period of myocardial ischemia (Fig. 37.2).

Warm (37°C) cardioplegia may also be used after aortic unclamping to restore rhythm and improve hemodynamics in the unstable patient following cardiac surgery. When used for impaired hemodynamics, the left ventricle requires venting to reduce distention and myocardial stress. The antegrade flow is given for 5 to 10 minutes.

**ANTEGRADE/RETROGRADE PERFUSION: INTERMITTENT OR SIMULTANEOUS?**

A cardioplegic perfusate requires even distribution. Adding retrograde perfusion improves subendocardial perfusion, avoids ostial cannulation during aortic valve procedures, limits removal of retractors during mitral procedures, and permits flushing of air and atheroma during coronary reoperations. Transatrial coronary sinus cannulation allows safe and rapid retroperfusion into the coronary sinus and has become widely adopted. Experimentally, right ventricular nutritive flow appears limited, thus hypothermia is essential to lower oxygen demand and provide effective right ventricular protection. Clinical studies show that switching from antegrade to retrograde perfusion increases oxygen uptake and lactate washout, indicating that each mode perfuses different areas. Therefore, both antegrade and retrograde perfusions are required (Fig. 37.3).
Fig. 37.1. (A) Left ventricular oxygen requirements of beating nonworking, fibrillating, and arrested hearts from 37°C to 22°C. Note the lowest requirements during arrest. (B) The left ventricular oxygen requirements of a beating working and an arrested heart at 37°C, 22°C, and 10°C. Note in panel A the low oxygen demands of arrest and in panel B the negligible change between 22°C and 10°C as the heart warms from collateral flow. Panel B shows higher demands than panel A if electromechanical activity recurs when systemic perfusate washes out the cardioplegic solution.

Fig. 37.2. (A) Left ventricular function in normal hearts subjected to 4 hours of aortic clamping with cardioplegia with blood every 20 minutes compared with depressed function after 45 minutes of normothermic arrest without cardioplegia. The type of protection is more important than the duration of aortic clamping. (B) Left ventricular function when jeopardized hearts undergoing 45 minutes of normothermic ischemia are subjected to two more hours of aortic clamping. Note (1) no further improvement when only cold cardioplegic perfusate is given over the 45-minute arrest period and (2) progressively increased recovery when the cardioplegic solution is supplemented with warm glutamate and aspartate during induction of cardioplegia and reperfusion with intermittent cold doses of blood every 20 minutes of supplemental aortic clamping. These data suggest the value of amino acid enrichment in jeopardized hearts. LAP, left atrial pressure; SWI, stroke work index.

The limitations of antegrade and retrograde delivery were first overcome by using both antegrade and retrograde perfusions intermittently. It is possible to simultaneously deliver retrograde cardioplegia via the coronary sinus and antegrade cardioplegia via direct ostial or vein graft infusion. Myocardial venous hypertension is prevented by drainage through the Thebesian veins. Studies document the safety of simultaneous vein graft and coronary sinus perfusion.

**INTERMITTENT/CONTINUOUS INFUSION**

Continuous cardioplegic perfusion has been advocated to avoid ischemia by antegrade or retrograde delivery, but adequate protection may not be achieved at usual flow rates and vision becomes obscured during infusion. A quiet/dry field requires “intentional” ischemia by intermittently stopping the flow of cardioplegic solution. Intermittent replenishment restores hypothermia, maintains electromechanical arrest, flushes accumulated metabolites, and counteracts acidosis and edema. Initially, the heart is arrested with high-dose potassium (20 to 40 mEq/L) blood cardioplegia (Table 37.1), and low-dose cold potassium (8 to 10 mEq/L) blood cardioplegia (Table 37.2) is used for intermittent repeat doses. Such reinfusions (every 15 to 20 minutes) are often retrograde, directly into the aorta or, via the each coronary ostium. Cold blood with a hematocrit of
Fig. 37.3. Myocardial metabolic changes in coronary patients when administration of the cardioplegic induction solution is converted from antegrade to retrograde. Note the increase in myocardial oxygen uptake, glucose uptake, and lactate production, suggesting different areas of perfusion by the antegrade and retrograde methods of delivery. This implies an advantage to both methods. A-V, arteriovenous.

approximately 20% is infused at a pressure of <40 mmHg and infused for a duration of 2 minutes.

At the completion of the cardiac procedure, controlled reperfusion is achieved by administering a dose of warm cardioplegic (“hot shot”), administered either antegrade, retrograde, or both. This can be followed by a continuous infusion of warm blood into the aortic root while the cross-clamp is still in place at a flow of 300 to 350 ml/min with a pressure of ≤80 mmHg. The aortic clamp is released within 5 minutes after adequate contractility is observed.

**CANNULAS AND DEVICES FOR DELIVERING AND MONITORING ANTEGRADE/RETROGRADE AND SIMULTANEOUS ANTEGRADE/RETROGRADE CARDIOPLEGIA**

All operations include the use of a cardioplegic heat exchanger for cold and warm perfusion (Fig. 37.4) cannulas for
2 minutes at a rate of 200 ml/min. In coronary bypass procedures, additional antegrade cardioplegia is hand delivered through the saphenous vein graft. The proximal vein graft proximal anastomosis is completed. Therefore, subsequent antegrade doses are delivered via the completed graft(s). All proximal grafts are performed during the cross-clamp period.

Retrograde Cannula

Transatrial approaches permit coronary sinus cannulation without right heart isolation. Cannulation is best performed before venous cannulation to avoid the venous cannula obstructing the path the retrograde cannula traverses to easily access the coronary sinus ostia. This is usually performed under ECHO guidance. We use a malleable stylet and inflating balloon cannula. A high atrial 4-0 purse-string suture is placed from the right side of the operating table (Fig. 37.6). The cannula should always enter the coronary sinus easily. The cannula is advanced 2 to 3 cm within the coronary sinus. The position is confirmed with ECHO images, the presence of dark blood emerging from the cannula, and the appropriate antegrade and retrograde delivery and a monitoring-infusion system. The system we use is shown in Figure 37.5. This has been found to be the simple, yet effective way for delivering and monitoring cardioplegia in conventional cardiac cases.

The main cardioplegia line is connected to a three-way stopcock. From here, the cardioplegia is set with branches allowing either antegrade flow or retrograde flow. The retrograde catheter has a port to transducer pressure allowing measurement and display of the waveform. The stopcock allows alternating between antegrade and retrograde flows.

Antegrade Cannula

An antegrade cannula is placed high in the ascending aorta below the proposed site of the aortic cross-clamp. This site is not used as a proximal graft site. A 4-0 purse-string suture with a tourniquet is used to secure the cannula and eventually tied at the end of the procedure, and oversewn to ensure hemostasis. After commencement of cardiopulmonary bypass, the heart should empty, as indicated by the collapse of the pulmonary artery, indicating good systemic venous drainage. The aorta is clamped, and antegrade cardioplegia is delivered for
"ventricularization" waveform that is transduced from the retrograde pressure measuring line.

Cannulation on partial bypass is done with the right atrium slightly distended to keep the coronary ostium open. Either ECHO-guided techniques or finger palpation can be employed to guide the retrograde cannula into position. Failure to intubate the coronary sinus is rare (1% to 2%) and indicates a fenestrated Thebesian valve or a flap over the ostium. Occasionally, the cannula fails to advance because it has gone into the posterior descending vein (Fig. 37.7). Alternatively, bicaval cannulation can be used. The right atrium is opened with a small incision and cannulation is performed directly after the flap is retracted or the Thebesian valve is opened. If the right atrium is open, a purse-string suture around the coronary sinus prevents reflux. This direct approach is preferred when the right atrium is open for tricuspid repair/replacement; transseptal approach to the mitral valve and biatrial MAZE procedures. The cannula is pulled back to the purse string to allow perfusion of proximal veins entering the sinus and allow cryotherapy to the mitral annulus and coronary sinus without the cannula interfering.

During retrograde infusions, the posterior descending vein fills readily with oxygenated blood, which confirms an extensive myocardial venovenous collateral network. The cannula is withdrawn slightly if there is failure to fill the posterior descending vein or if there is no egress of blood from the right coronary ostium or open right artery during aortic or coronary operations. This dark blood signifies nutritive flow despite some shunting into the right atrium with inflating balloons. The blood becomes red, which reflects adequate perfusion. This is especially important if normothermic continuous cardioplegia is delivered.

**Coronary Sinus Injury**

The coronary sinus can be injured due to forceful cannulation or continued administration of cardioplegia when coronary sinus pressure exceeds 50 to 60 mmHg. This can occur while the heart is elevated during circumflex artery grafting. The perfusionist notes high pressure, and then low pressure as a consequence of acute perforation, or the surgeon sees red blood accumulation within the pericardial well during infusions. Perforation can be repaired directly with 6-0 prolene sutures or with a pericardial patch if there is concern that the repair will constrict the coronary sinus. Hematomas can sometimes be left unattended and observed because low venous pressure allows self-containment after heparin reversal.

**Monitoring Pressure**

Measuring infusion pressure avoids edema and endothelial damage. During retrograde infusion, measurement of pressure verifies correct placement of the coronary sinus cannula.

**Retrograde Pressure**

Coronary sinus pressure ranges from 30 to 40 mmHg at an infusion rate of 200 to 250 ml/min. A coronary sinus pressure of >50 mmHg means improper positioning or cardiac retraction that kinks the venous system. This is treated by reducing the flow rate immediately, repositioning the catheter, and resuming flow. Balloons should not be moved during infusion because of coronary sinus wall traction and possible injury. Coronary sinus pressure of <20 mmHg implies that the balloon is not inflated or not occluding the coronary sinus. The cannula tip and balloon should then be palpated and repositioned. Other causes of low pressure are: (1) persistent left superior vena cava (SVC), (2) failure of balloon inflation, and (3) rare left atrial unroofing of the coronary sinus noted during mitral procedures. The presence of a left SVC is usually determined before cardiopulmonary bypass, and the vessel is occluded with a tourniquet only if an intact innominate vein is present. If the innominate vein is absent, only antegrade cardioplegia is used, to avoid myocardial under perfusion.

**CARDIOPLEGIC SOLUTIONS**

Two important basic principles of blood cardioplegia are: (1) blood optimizes the rate of aerobic metabolism and (2) oxygen uptake occurs over time, so that infusion duration is more important than dose. Delivery at a fixed pressure for too short a time (especially with warm infusions) deprives the myocardium of the benefits of a full dose. The setup should include flow clamps to direct antegrade or retrograde flow of the cardioplegic solutions for induction, maintenance, and reperfusion. In addition, the option to flow the cardioplegia through an "inline" white blood cell filter to add leukodepletion to the cardioprotective strategy should be considered.

The following guidelines are used for flow rates in normal hearts and are increased by 50 to 100 ml/min for hypertrophied hearts (Table 37.3). Many formulations...
with various additives are used with excellent results. High-dose potassium (20 to 30 mEq/L) solution that contains components has been described previously. It arrests the heart promptly during either warm or cold induction and remains available if electromechanical activity recurs. Enrichment with amino acids (glutamate/aspartate) is useful in high-risk patients (Table 37.1), those with low output, ischemia, or hypertrophy. It is switched to the low-dose, nonenriched potassium solution immediately after arrest with cold induction to limit hyperkalemia. The low-dose potassium (10 to 15 mEq/L) solution (Table 37.2) is used for maintenance doses during cold cardioplegic infusions and does not contain amino acids. At the completion of all cardiac repairs, all patients receive a terminal warm cardioplegic perfusate (“hot shot”). This solution is substrate enhanced in patients with poor ventricular function or long cross-clamp times in complex procedures. In transplant patients, an additional 3 to 5 minutes of noncardioplegic warm normal blood (leukocyte depleted) with the aorta clamped is given. During infusion of the warm reperfusion, it is not uncommon to observe a mild degree of transient hypotension due to vasodilation.

Normocalcemic blood from the extracorporeal circuit is added to the cardioplegia solution. In adult patients, if citrated solutions (CPD) are used; calcium should be added to the cardiopulmonary bypass circuit prime prior to weaning from bypass. This avoids unintentional hypocalcemia, which can damage the membranes of the sarcolemma. In pediatric patients, systemic hypocalcemia occurs when the pump is primed with citrated blood. Consequently, no calcium is added until the end of the procedure, when the calcium concentration is normalized before bypass is stopped.

**CORONARY BYPASS PROCEDURE**

During coronary bypass, the body’s core temperature is cooled and kept between 32°C and 34°C. The heart is arrested with high-potassium cold blood cardioplegia in elective low-risk operations with good ventricular function. In cases where acute ischemia is present or in cases of severely depressed systolic function, high-potassium substrate enriched warm blood cardioplegia (“warm induction”) is used initially to arrest the heart. The administration of substrates in this situation has been proven to aid in the recovery of function after surgical repair. After the warm induction, low-potassium cold blood cardioplegia is infused into the aortic root and/or retrograde into the coronary sinus. Intermittent low-potassium cold blood cardioplegia is used during the course of the grafting (Table 37.3). The ventricle is palpated; short axis view of the transesophageal echocardiography (TEE) and PA pressure are observed because cardiac distoration or aortic insufficiency (low aortic root pressure) may harmfully distend the ventricle. Similarly, retraction of the heart during retrograde delivery raises coronary sinus pressure by kinking the venous system. If pressure exceeds 50 mmHg, flow is reduced.

Following cardioplegic arrest, all anastomoses are constructed in a dry operative field using distal/proximal grafting in sequence. The right coronary graft is constructed first because retrograde nutritive perfusion is limited. Retrograde perfusion (200 ml/min for 2 minutes) is started after the last suture is placed in the first distal anastomosis with the suture line patulous to allow de-airing of the coronary artery with blood. The flow clamp connected to the graft is opened to evacuate air from the graft and to provide simultaneous graft antegrade and whole-heart retrograde cardioplegic perfusion while the suture is tied. The antegrade injection can be given by hand injection to remove air from the graft, test for anastomotic leaks, and determine resistance to runoff.

The vent is closed to distend the aortic root. The graft length is facilitated by holding the distented vein or arterial graft adjacent to the pericardium taking into account pulmonary artery distention when the heart will be full. A no. 11 blade is used to make a small incision where the proximal will be attached to the aorta, and a 4.0- to 4.5-mm punch is inserted into the small aortotomy and deployed. The proximal anastomosis is performed. Then, antegrade cardioplegia is administered allowing the root to fill with blood, evacuate any air, and the suture is then tied. Newly constructed grafts perfuse the heart after each proximal connection. The next distal graft is then constructed in a dry operative field while the aorta is vented. The sequence is repeated for each distal and proximal anastomoses, leaving one proximal graft to be connected to the aorta after the final distal left internal mammary artery (LIMA) anastomosis is constructed. Systemic rewarming is started while the LIMA anastomosis is begun. After the LIMA is anastomosed to the anterior descending artery, antegrade warm cardioplegia is delivered for 2 minutes initially and then retrograde.

After cross-clamp removal, the aortic root is vented and the heart usually begins to resume contraction. Clamps on the LIMA graft is removed just before starting the warm cardioplegia. When antegrade flow is started to de-air the aortic root, the grafts are de-aired with a fine needle vent hole to prevent air embolus.

In combined valve/coronary procedures, distal grafts are first placed. The valve is then replaced or repaired. Every 15 to 20 minutes, maintenance cold blood is delivered through retrograde catheter. All the proximal anastomoses are performed lastly with the aorta still cross-clamped. The warm (2 to 4 minutes) cardioplegic reperfusion is started. After the high-potassium cardioplegia is washed out, the heart begins to contract slowly.

The antegrade infusion of warm cardioplegia or warm blood is then infused into the aortic root with the cross-clamp in place at a flow of 250 to 300 ml/min. The heart resumes vigorous contractility within a couple of minutes. The aortic clamp is then released, and the aorta is vented.

### REPEAT CARDIAC SURGERY

The integrated cardioplegia method has been found to be particularly useful in repeat operations. In coronary bypass operations, a generally accepted rule is that old grafts should be left undisturbed. This “no-touch” technique prevents embolization of friable atherosclerotic debris into the distal vasculature.

After sternotomy, only the aorta and the right atrium are dissected free of surrounding adhesions. After canulation and institution of cardiopulmonary bypass, the retrograde cannula is inserted. The aorta is clamped and flow through a patent

LIMA is occluded. Induction cardioplegia or cold blood cardioplegia is administered into the aortic root to arrest the heart. Retrograde cardioplegia follows or is instituted early if there is ventricular distention.

After patent atherosclerotic vein grafts are divided proximally, the heart can be safely freed of surrounding pericardial adhesions. This avoids compression of old vein grafts and embolization. The added time of ischemia is only about 10 minutes, and the hemodynamics is not compromised by avoiding mobilization by dissection of the beating heart before arrest. Distal and proximal grafts are constructed in sequence as with all coronary operations. The single aortic cross-clamping technique avoids compression of old grafts and ischemia that can be induced by the side-biting method, in which graft flow is temporarily interrupted.

Clinical outcomes with this method in repeat coronary bypass grafting have demonstrated no increased mortality, even in patients with markedly reduced systolic function preoperatively.

MYOCARDIAL PROTECTION DURING MINIMALLY INVASIVE CARDIAC PROCEDURES

Although more cardiac procedures are being offered through minimally invasive incisions, it is imperative that the operation be as safe and more importantly have the same outcomes as traditional sternotomy approaches.

In this section, we will describe cardioplegia set-up and techniques for minimally invasive aortic valve procedures as well as for mitral valve and tricuspid valve operations.

With minimally invasive aortic valve operations, I choose to use a small (3 inch) upper sternotomy incision. The sternal incision extends from the sternal notch and ends at the level of the right third/fourth intercostal space. This exposes the entire ascending aorta and aortic root. Through this same incision, I have performed ascending and arch aortic aneurysms as well as aortic root operations, including valve-sparing root procedures.

With regard to aortic cannulation, the placement of the antegrade cardioplegia catheter is unchanged from my sternotomy approaches. The retrograde cardioplegia catheter is placed through a purse-string suture in the right atrium just below the appendage cannulation.

The catheter is then placed under ECHO guidance into the coronary sinus. Once cannula placement is confirmed with ECHO, waveform tracing, and dark blood return, the purse string is snared and the cannula position is secured. After the retrograde catheter is positioned, the venous cannula is placed. It is important to place the retrograde cannula first to avoid the pathway to the coronary sinus becoming obstructed by the venous cannula.

If the right atrium is not visible due to the upper sternotomy incision or that cannulating the right atrium is difficult because of exposure, then I cannulate the femoral vein percutaneously with a long venous 25F cannula. If there is not a contraindication, I prefer to cannulate the right femoral vein. The cannulation is performed using the Seldinger technique and assistance is gained from ECHO that verifies the wire placement and the advancement of the cannula over the wire into the right atrium. As with central venous cannulation, having the retrograde catheter in place prior to placement of the long venous catheter eases placement and avoids dislodgment of the retrograde catheter.

Shortly after the initiation of cardiopulmonary bypass, the aortic cross-clamp is applied and the TEE transgastric short axis view of the heart is monitored for ventricular distention. After 500 cc of pressure-controlled antegrade cardioplegia and cardiac arrest, the stopcock is turned and retrograde cardioplegia with a sinus pressure of approximately 40 mmHg is administered for a total dose of 1.0 to 1.2 L.

Throughout the case, retrograde cardioplegia is delivered at least every 20 minutes or at optimal times to ensure a dry field. While the aortotomy is being closed, the perfusionist prepares the warm reperfusion dose. Prior to tying the sutures, the retrograde followed by antegrade warm cardioplegia is given. Air is allowed to evacuate the aorta and the sutures are secured. After the warm cardioplegia is administered, the aortic root is vented with the head of the patient dependent. The cross-clamp is removed and the heart is allowed to return to sinus rhythm.

MYOCARDIAL PROTECTION DURING ORTHOTOPIC HEART TRANSPLANT

The donor heart is arrested with cold blood cardioplegia solution. The heart is steriley wrapped for cold storage transplant. Reliable myocardial protection for 4 to 5 hours can be expected.

During implantation, topical ice slush with an insulating pad protecting the left phrenic nerve provides myocardial protection. After completing the anastomosis of the left atrium, a 10F catheter is guided from the right superior pulmonary vein across the body of the atrium and into the left ventricle. Cold (4°C) plasmalyte is allowed to infuse to cool the endocardium. The plasmalyte solution (Table 37.4) will exit from the donor aorta and is continued during the pulmonary artery and aortic anastomosis.

The pulmonary artery sutures are not tied to allow venting of the right ventricle during weaning from cardiopulmonary bypass. After the SVC and IVC anastomoses are completed, warm substrate-enhanced antegrade cardioplegia is given at a controlled reperfusion pressure of less than 80 mmHg for 4 minutes followed by warm blood (leukocyte depleted) for 3 to 4 minutes. The aortic cross-clamp is removed and the aortic root is vented.

TEE of the cardiac chambers ensure complete air removal. The pulmonary
artery suture line is tied as the wean from CPB is completed. A left atrial pressure line is inserted to monitor directly the left atrial pressure. The TEE is essential to monitor both left and right ventricular functions.

**MYOCARDIAL PROTECTION DURING AORTIC ROOT REPLACEMENT**

The myocardium must be carefully protected during extensive and long operations on the aortic root, as encountered with ascending aortic aneurysm or dissection. Here, the coronary ostia are often isolated for reimplantation into a graft. Intermittent cardioplegia can be administered directly into these ostia buttons, but care must be taken to avoid injury, particularly if operation is indicated because of dissection. Occasionally, when dissection extends down the right coronary or torsion cannot be prevented by extensive right coronary mobilization, grafting the right coronary artery with saphenous vein is helpful.

Cardioplegia should be administered intermittently retrograde and antegrade. This permits maximal distribution throughout the myocardium and does not interfere with the operation. The aortic root and ascending aorta can be repaired with ease in a dry field. After the root has been reconstructed and the left coronary ostia reimplanted into the graft, the graft is clamped distally and antegrade cardioplegia is infused. This allows left main cardioplegia to be given, checks for anastomotic leaks, graft orientation for the distal anastomosis and the site for implantation of the right coronary button. A final retrograde and antegrade dose of warm substrate-enhanced cardioplegia is administered for 2 to 4 minutes.

**MYOCARDIAL PROTECTION FOR VENTRICULAR RESTORATION**

Ventricular remodeling is an approach used in rebuilding the ventricular chamber in congestive heart failure patients. These patients are in the highest risk category with low EF and normally undergo coronary grafting, and approximately 25% need mitral valve repair. Both coronary artery bypass grafting (CABG) and mitral repair are accomplished with the previously described antegrade and retrograde methods of warm induction, cold maintenance, and substrate-enhanced reperfusion.

After removal of the aortic clamp, the reconstruction of the spherical left ventricular chamber into an oblique shape is performed. The method of protection is the “beating open” technique. Competence of the aortic valve together with ventricular venting via the left superior pulmonary vein avoids ventricular filling during repair.

Aortic perfusion pressure is kept at >75 mmHg because both experimentally and clinically, this higher pressure improves subendocardial perfusion: An improvement in the force of twisting is usually observed when perfusion pressure is increased. Restoration, with continuous perfusion, is always done after coronary grafting is completed to take advantage of the improved flow provided by the CABG procedure. Ventricular palpation with the beating method is very useful in the thick-walled akinetic heart, in which visual distinction between scar and viable muscle is difficult, especially if there is trabecular scar, or in the early phases after infarction when there is no evidence of scarring. Other advantages include (1) limiting ischemia by allowing ongoing coronary perfusion in severely dilated hearts during early learning curve, when the time period of restoration may be prolonged, (2) continuous perfusion to repay the “ischemic debt” after prolonged aortic clamping with cardioplegic protection was needed during the CABGs and mitral repair phases of the procedure, and (3) more rapid discontinuation of bypass as the reperfused heart undergoes a long period of nutritive flow during restoration. Consequently, the beating method offsets the interval of “resting the heart” by prolonging the end of the procedure.

Determination of preoperative aortic insufficiency by ventriculogram or intraoperatively by ECHO is critical because only a small amount (i.e., 500 ml/min) will obscure the field. We normally use the beating technique. If aortic regurgitation is anticipated, the aortic clamp is left in place; proximal grafts are perfused via a Y connector rather than connected to the aorta, the internal mammary artery graft is opened, and antegrade normal blood perfusion is delivered to the beating heart during repair as shown in Figure 37.8.

**CONCLUSION**

Myocardial management as described is useful in all adult cardiac procedures by allowing them to proceed smoothly and more rapidly than usual because there is minimal interruption or delay for infusion of cardioplegic perfusate or noncardioplegic blood reperfusion. The duration of cardiopulmonary bypass is actually shortened while one simultaneously takes advantage of the benefits of different methods that compliment effective and efficient myocardial protection strategies. Ongoing studies continue to explore the incorporation of additional cardioprotective methods such as preconditioning agents, white blood cell filters, oxygen radical scavengers, endothelium-enhancing agents, and molecular factors that will further improve the safety of ischemic intervals and limit reperfusion damage.

The myocardial protection methods presented reflects the author’s current approach with over 35 years of research and clinical experience. However, there is no one unique technique of myocardial protection. The individual must understand the basic science and principles that have evolved over the past several decades. The individual surgeon must have a consistent and adaptable approach. The techniques must be flexible to allow for intraoperative flexibility to deal with specific clinical situations. Team communication with the perfusionist, the operating room nurses, the surgical assistants, and the anesthesiologist is essential. However, even the best techniques of myocardial protection do not make up for a normally perfused heart. No matter what technique is used, time is of the essence. Time management and a coordinated cardioplegia approach that compliments and does not delay the operative flow must be the goal of the operating surgeon.
Fig. 37.8. Beating heart myocardial protection during ventricular respiration in a patient with aortic insufficiency. Note the clamped aorta, with perfusion via the internal mammary artery, vein grafts, and retrograde via the coronary sinus. This method is used with either anterior or inferior repairs.

**EDITOR’S COMMENTS**

Dr. Odeh and Dr. Shemin have done an outstanding job presenting a thorough approach to myocardial protection. I believe their descriptions are comprehensive and their overall approach will allow for very safe cardiac surgery. It is extraordinary how things have developed over the last 20 years. It was not unusual at one time that at least 10% of the patients would have required an intra-aortic balloon pump to come off bypass. This almost never occurs presently in elective or either urgent cases due to our myocardial protection strategies. I believe one should go by the book and have a careful orchestrated approach to myocardial protection as the authors have described.

Our group has two slight differences from the techniques discussed here. The authors have discussed using antegrade and retrograde cardioplegic simultaneously. They mentioned that there are studies suggesting this could be done safely. I have at least theoretic concerns about this and we have avoided doing this at our institution. I do not think there is any issue with giving antegrade followed by retrograde.

The second issue relates to redo surgeries. The authors describe controlling the patent internal mammary artery graft to allow for better protection. I think this is okay but we have demonstrated that leaving an IMA open in patients requiring valve surgery is a nonissue. We have noted that there is less incidence of injury to the internal mammary artery using this technique, and we have found no issues with protecting the heart even with the IMA perfusing. In fact, it may provide better protection overall because of continuous blood being given to the left anterior descending distribution.

**SUGGESTED READINGS**

Quality improvement endeavors within the field of cardiac surgical care have made substantial progress over the last 40 years. A key aspect that has promoted improvement in the processes, structures, and outcomes in cardiac surgical care is the development of multi-institutional databases to monitor clinical risk-adjusted outcomes following cardiothoracic surgery. Quality improvement database reports offer several inherent advantages to a cardiothoracic surgeon in clinical practice. Using statistical prediction models, reports generated from complete and high-quality databases offer a unique assessment of the interactive effects of multiple risk factors on outcome.

The majority of these cardiac surgery database initiatives began by focusing reports upon relatively crude measures of unadjusted operative (30 days) mortality as their primary outcome criteria. Since the mid-1990s, there has been a progressive increase in the level of sophistication in the databases. For example, risk models can be constructed from a list of preoperative variables, and these models can be used to predict the likelihood of adverse outcomes. Whereas database outcomes initially focused on mortality, more recent efforts expand the focus for risk-adjusted outcomes to also include major morbidity as well as risk-adjusted efficiency outcomes such as length of stay and cost. Databases offer the opportunity for both feedback and information exchange; facilitating the comparison of institutions, providing data to local clinical care teams to self-assess performance, and coordinating future improvement strategies. This exchange offers, in turn, the potential to further improve the processes, structures, and outcomes of care in cardiac surgery.

**HISTORICAL CONSIDERATIONS**

Local databases have been used by many institutions for more than 40 years. For example, hospital-based databases have been used by Duke University, the Cleveland Clinic, the Mayo Clinic, and others to monitor volume and mortality statistics within their institutions. The first large, multi-institutional monitoring of cardiac surgery outcomes began in the Department of Veterans Affairs (VA) with the establishment of the VA Cardiac Surgery Consultants Committee (CSCC) in 1972. Under a congressional mandate, the VA semiannual reports were combined with ongoing surveillance work toward the goal of assuring the quality of cardiac surgical care in the VA system. Until 1988, the CSCC used unadjusted mortality and volume as the main parameters to judge outcomes. Takaro and colleagues analyzed the VA experience from 1975 to 1984 and noted that the annual volume of cardiopulmonary bypass surgery rose from 3,000 to more than 6,400 procedures. Correspondingly, the observed mortality rate for coronary artery bypass procedures dropped from 4.7% to 3.6%. They noted that patient-related comorbidities accounted for most of the operative mortality, but advances in surgical and medical techniques also may have played an important role in this mortality rate reduction.

On March 12, 1986, the Department of Health and Human Services Health Care Financing Administration (HCFA) released to the public raw mortality data for coronary artery bypass grafting (CABG). This report actually listed hospitals that had mortality rates for Medicare patients undergoing CABG that were in excess of predicted mortality rates. Although these data were to be used originally for state peer-review organizations as a quality improvement tool, HCFA was forced to release these data through the Freedom of Information Act. These mortality rates were unfortunately not risk adjusted for clinical patient risk factors. In addition, diagnostic categories were grouped together without comprehensive clinical patient-specific risk adjustments related to severity of disease and comorbidities. Furthermore, the public release of these data prompted widespread concern that nonrisk-adjusted mortality could not offer an accurate reflection of the caseload mix, and relative outcomes within an individual program. Without appropriate patient-specific clinical risk stratification, accurate comparison of cardiac surgery outcomes between programs was widely perceived not to be useful for patient care, program management, or policy decisions. This action by HCFA served as a strong stimulus for the Society of Thoracic Surgeons (STS) to initiate its own cardiac surgical database with risk-adjusted methods.

In 1987, the VA Cardiac Surgery Advisory Group, then called the VA Cardiac Surgery Consultants Committee, was also concerned with the use of unadjusted operative mortality and volume as major quality indicators for the approximately 45 VA cardiac surgery programs. Using the logistic regression method approach developed by the Collaborative Study in Coronary Artery Surgery, Drs. Hammermeister and Grover developed a multivariable risk model using clinical and angiographic predictors of 30-day operative mortality separately for coronary artery bypass procedures and valve plus other operations. The method included capturing data on all cardiac surgery procedures performed using a single-page data sheet (originally of 52 data elements) including patient-specific clinical risk factors, cardiac catheterization assessment data, operative details, and a set of both mortality and major morbidity outcome variables. These initial efforts proved successful in the attempt to “level the playing field” by accounting for the individual patient risk factors that could play a role in determining outcomes after cardiac surgical procedures (according to the first VA report). Based on these early events, two large national databases, the STS National Adult Cardiac Surgery Database and the VA Cardiac Surgery Database, emerged in a complementary and synergistic manner to provide routine reports of cardiac surgical practices for their use in their own local quality improvement endeavors. Similarly,
large regional databases also evolved, including (but not limited to) the Northern New England Cardiovascular Study Group (NNE), the New York State databases, and more recently state databases in California, Massachusetts, and Pennsylvania.

DATABASE CONSTRUCTION

The factors that may influence the differences in outcomes include variations in patient risk factors, in the processes and/or structures for the clinical care provided, as well as random chance. Conceptually, there are different categories of patient risk characteristics that may influence cardiac surgical outcomes including patient demographic factors, socioeconomic factors, severity of cardiac disease, comorbidities, and patient lifestyle/health behaviors. As a general rule, patient risk factors should be assessed as close to the starting time frame for the cardiac surgical procedure as possible to most accurately and reliably evaluate the patient’s inherent risk. Using statistical modeling approaches, risk stratification for a given procedure holds constant the patient-specific characteristics that may influence the likelihood of specific patient outcomes. Risk-adjusted outcomes provide indirect measures to begin exploring the potential differences for quality of care.

Virtually all of the national, regional, and local cardiac surgical databases provide predictive risk stratification—that is, an estimation for a patient with a prespecified risk profile what is the risk of having an adverse cardiac surgical event occur. Surgeons must, however, be aware of the limitations and factors pertaining to the design, construction, and management of a particular database if it is to be optimally utilized. Of primary importance are the completeness, accuracy, reliability, timeliness, sensitivity to change, and integrity of the data entered. “Garbage in = garbage out” is operative in considering any analysis of a database. Ideally, all patients receiving a cardiac surgical procedure should be entered for analysis and the adverse outcomes (such as 30-day operative mortality) appropriately validated. For any given patient record, the data submitted must also be internally consistent. For example, patients entered into the database as needing emergent operations should have firm clinical data supporting the need for such a classification. Both intrafield and interfield edit checks may be used to evaluate data quality discrepancies. Finally, standardized definitions (with training for the data capture team) are important for all data elements. Common inconsistencies in application of definitions have been demonstrated for patient-related outcomes, such as perioperative morbidities, where the use of different diagnostic test assessments is not consistently performed across all settings. Surgeons should be aware of the important aspects of the management/operation of any given database, including the following:

1. Which outcomes are examined, and are definitions for the measured variables standardized? Mortality, for example, is the most widely used outcome because of its importance and it is readily available from hospital records. Such a dichotomous variable would seem relatively standard. However, some databases measure in-hospital mortality, whereas others track 30-day mortality after CABG (including both in-hospital deaths and deaths that occur within 30 days postsurgery). Other important outcome variables to monitor commonly include the occurrence of major complications (infection, stroke, prolonged ventilation, renal failure, etc.), cost, and length of hospital stay. These are more difficult to measure because complications may not be uniformly recorded across sites. Standardized definitions for these major morbidity events are rigorously defined by the STS and VA cardiac databases.

2. What is the intent of the data analysis? The database may be designed to provide a predicted outcome for a given patient or to compare surgeon-specific or program-specific outcomes. In addition, outcomes analysis may be used to drive national policy decisions or managed care accreditation. Discussions have been initiated also about using risk-adjusted outcomes for physician profiling and credentialing.

3. How are the data collected? Input for databases may be gathered in a retrospective, concurrent, or prospective manner. Depending on the database, data acquisition may be mandatory (VA database) or voluntary (STS database). Data acquisition and entry may be collected by members of the patient care team or by independent data collectors. For example, in the VA database, data are collected by nurse investigators who are independent of the surgical team. It is believed that independent collection of such data may result in more thorough and unbiased reporting (e.g., self-reporting for perioperative complications may not be consistently assessed and/or uniformly recorded across surgeons).

4. How are the missing data treated? Any large database will have incomplete data elements. Missing data happens more commonly in databases where the data are gathered and/or entered retrospectively. If the outcome of interest is missing, then the records with missing outcome data must be discarded because no reasonable method exists that is well accepted to impute outcomes. Occasionally, there are enough missing data elements within any specific record to justify dropping this specific case. Common imputation techniques derive a value to be inserted for the missing variable based on values for other data fields for that same patient, in context of the data gathered for other patients. As the completeness rates for cardiac surgery databases have increased, however, the need for complex imputation techniques has begun to diminish.

5. How did the predictive model perform that was generated from the database? Construction of a predictive model typically involves several steps. First, a conceptual model is generated that identifies the clinically relevant variables (e.g., risk factors) that are thought to be associated with a particular outcome (e.g., mortality). In context of the previous literature published within the field, these clinical models are constructed by a panel of experts. After these risk factors have been identified, rigorous definitions must be used to standardize the data collection. After all database completeness, accuracy, and reliability verifications (including any required data record updates), both univariate and multivariate analyses may be performed for a procedure, for a selected population of patients, and for prespecified outcomes to determine which of these risk factors are statistically associated with adverse patient outcomes. As part of the univariate screening, the outcome rates for patients with a given risk factor are compared with the outcome rates for patients without the risk factor. The number of patients required for such an analysis varies based on the nature and frequency of the outcome studied, the number of patient risk variables planned for evaluation, and the statistical approach planned. Based on the rule that in logistic regression analysis, there should be no more than 1 risk factor assessed per 10 to 15 adverse
events, if ~10 risk variables are used, >5,000 cases are required to develop a logistic regression model for CABG-only procedure, assuming an average mortality rate of <3%.

After univariate screening analyses have been performed, a multivariable predictive model is next generated. In the majority of the cardiac surgical literature, the endpoints analyzed for risk models have included risk-adjusted mortality or presence/absence of major perioperative morbidity. For any dichotomous modeling endpoint, the analytical technique originally used by the STS to generate a predictive equation was initially based on Bayesian theory to address the inherent challenges in a voluntary database related to missing data. However, the STS switched to multivariable logistic regression in 1997 when the data record completeness and quality improved such that the performance of the logistic regression approach was determined to be more robust. For dichotomous endpoints (e.g., 30-day operative mortality), the Northern New England Cardiovascular Consortium, VA, New York State, California State, and Massachusetts State databases have also used multivariate logistic regression as the most common risk modeling approach.

Multivariate logistic regression is a statistical technique that can be used for either explanation (to understand associations between risk factors and outcomes) or prediction (to estimate risk for new and different populations). To apply the logistic regression equation for prediction purposes, risk factors are normally entered into the mathematical equation for a given patient. Mathematically, application of the logistic regression equation to a specific patient’s data captured can yield the statistical probability for the adverse outcome of interest.

Before being actively used for quality assessment activities, the performance for any statistical modeling approach(es) employed should be thoroughly evaluated. For logistic regression models, the “predictive power” (or c-index) of the model describes the concordance of the outcome predictions in comparison to the actual outcomes observed. The c-index describes the area under the receiver-operating characteristic curve related to the true-positive rate (sensitivity) and the false-positive rate (1-specificity). For example, a c-statistic of 0.5 would indicate that the risk model has no better chance than flipping a coin of identifying “at risk” patients for adverse outcome events. Ideally, a predictive risk model will have a c-index of >0.70, meaning that on average 70% of the time that the outcome predicted by the model is accurate, leaving the remaining 30% subject to the unmeasured risk factors, the nature of the processes and structures of care rendered, as well as random chance.

Statistical risk models are best for predictions performed on large volumes of patient records, where the confidence intervals around the predictions may be relatively small, as compared with predictions made for a single patient where the confidence interval around the point estimate for risk prediction may be large. Given that it is virtually impossible for a single risk model to incorporate comprehensively all of the risk factors that are relevant to all patients, there commonly may be unmeasured risk variables (specifically, rare patient risk factors) that may predispose a given patient to an adverse event. The final predictive variables included in a logistic regression model, therefore, are generally those factors that have the largest impact and occur reasonably frequently. For example, a patient may have had chest radiation in the past, which can increase their risk of adverse perioperative outcomes. As chest radiation occurs infrequently, however, this risk factor may not be commonly placed upon the list of prediction variables that determine estimated operative morbidity and mortality. For this reason, statistical risk models may either underpredict or overpredict the risk for an individual patient, so that physicians need to take this into account when diagnosing unusual patient risk factors when deciding on appropriate therapy and discussing this with a given patient.

For logistic regression models, another key performance metric to be evaluated is the model’s calibration. Model calibration describes how well the model performs over the full range of risk estimates, as compared with the observed outcome rates. Models may work well for high-risk or for low-risk situations but not uniformly work well across all ranges of risk. A common metric used to assess logistic regression model performance related to calibration is the Hosmer–Lemeshow [H-L] test for “goodness of fit.” The H-L test is adapted from the Chi-square test, evaluating to what degree there is “no difference” in the predicted versus observed outcome rates across ordered risk categories (such as ordered deciles of risk). To be able to state that there is not a calibration challenge, therefore, the H-L test statistic’s P-value should be ideally >0.05—stating that there was no difference in calibration across the risk categories that were observed.

In addition to multivariable logistic regression for single endpoints, more complex regression approaches for multiple endpoints have recently been implemented by the STS. One notable example is the development of a comprehensive composite metric that assesses multiple aspects of quality rather than focusing only on risk-adjusted mortality. This acknowledges the fact that not all patients who survive CABG surgery have had equivalent quality procedures. The STS Database team and its Quality Measurement Task Force under the guidance of Dr. Shahian has developed a meaningful, NQF endorsed CABG Composite Score to assess the overall quality of care rendered. The results of this methodology are presented as both numerical scores and, for ease of consumer interpretation, as a “star” rating system. In the latter, programs whose results are estimated to have at least a 99% Bayesian probability of being superior to the STS average are awarded three stars (about 10% to 15% of all STS participant programs), whereas those with a similar probability of being worse than the STS average (again, about 10% to 15%) are awarded one star. The remaining or average quality programs are classified as two stars.

To calculate the STS CABG Composite Score for each hospital, the following four metrics were combined:

1. freedom from 30-day operative mortality (both any in-hospital death regardless of timing and any death within 30 days regardless of venue; risk-adjusted);
2. freedom from major morbidity (defined as the risk-adjusted occurrence of any one or more of the following endpoints: renal failure, reoperation, stroke, sternal wound infection, prolonged ventilation);
3. use of at least one internal thoracic arterial bypass graft conduit (considered as a “best surgical practice”); and
4. use of all recommended perioperative medications (preoperative beta blockade; discharge antiplatelet drugs, lipid-lowering agents, and beta blockade) (an “all-or-none” endpoint; considered as a “best medical practice”).

The above metrics were analyzed together in a hierarchical model in order to estimate success rates for each of the four metrics by a participant. A participant’s final composite score was obtained by averaging their four success rates. Albeit more complex analytically, this innovative
quality metric is multidimensional (evaluating simultaneously mortality, morbidity, and reflects compliance with what is considered the optimal CABG surgical and ischemic heart disease medical therapy practice) and fully risk adjusted. This intellectually elegant and clinically relevant composite metric provides an assessment of the quality metrics that hospitals can control (specifically their hospital’s compliance with best practices) while adjusting for the factors that hospitals cannot control (specifically, the risk characteristics of their patient population).

**CURRENT ADULT CARDIAC SURGERY DATABASES**

**New York State Database**

In response to the HCFA release of cardiac surgery data and as much as fivefold variations in mortality between hospitals, New York State organized a Cardiac Surgery Advisory Committee, which was charged with investigating issues related to quality assurance for cardiovascular disease. A clinical registry for cardiac surgery began collecting data in 1989 and one for percutaneous coronary intervention (PCI) began in 1992. This group developed a patient-specific cardiac surgical report form. This form reported demographic data, surgical procedures, admission and discharge dates, and information on risk factors, complications, and discharge status. Data forms are completed at each surgical program and forwarded to the Department of Health for analysis. Data reporting is mandatory.

The first report on these data was published in 1990 and described hospital mortality rates for 28 hospitals, 4 of which had significantly higher than expected mortality rates. The overall statewide mortality rate for cardiac surgery was 4.87%. Identifying these poor performing centers allowed site visits to occur to identify the quality-of-care issues. For example, Winthrop Hospital in New York had one of the highest risk-adjusted mortalities with the initial data. They were placed on probation that allowed them to hire a new chief of cardiac surgery, centralize all patients in one area, hire nurse specialists and physician assistants dedicated to cardiac surgery, review all cases preoperatively, and hire a dedicated team of cardiac anesthesiologists. These interventions allowed risk-adjusted mortality to fall from 9.2% to 4.6% to 2.3% between 1989 and 1991.

The surgeon-specific outcomes reporting has also had an effect on the cardiac surgery climate in New York state. A more recent study by Jha and Epstein covering the years of 1989 to 1999 reported that 20% of the surgeons in the lowest performing quartile abandoned cardiac surgery or relocated within 2 years of the report, whereas only 5% of surgeons in the top performing quartile did so. Interestingly, in the same study, the authors found that a higher risk-adjusted hospital mortality did not affect that hospital’s market share negatively.

A study comparing PCI to CABG in multivessel CAD was published in the New England Journal of Medicine in 2008. They compared the 18-month outcomes of patients meeting their inclusion criteria from 2003 to 2004. They demonstrated a statistically significant lower mortality and rate of repeat revascularization in the CABG group at 18 months.

Some studies have also been performed to answer the question of whether high-risk cases were turned away due to fear of excess mortality. A study by Omoigui et al. demonstrated an increase from 61.4 patients per year to 96.2 patients per year being treated at the Cleveland Clinic in the 10-year period before and after 1989. These patients transferred in the later decade were also sicker on average than those treated in New York State. Another study compared the preprocedural severity of illness of patients undergoing PCI in New York versus Michigan. They found lower rates of acute MI, cardiogenic shock, and congestive heart failure. As one would expect, the overall hospital mortality was much lower in New York, and risk-adjusted mortality was not significantly different. Both studies have their weaknesses and this remains a controversial and unresolved issue.

Despite these types of criticisms, the overall mortality in New York State continues to decrease. The New York State Database remains active and continues to identify significant independent risk factors for cardiac surgery and avenues to improve outcomes.

**Northern New England Cardiovascular Disease Study Group**

The Northern New England Cardiovascular Disease Study Group was organized in 1987 to help improve the quality, safety, and cost of cardiovascular interventions in the region. This group comprises representatives from 11 institutions performing cardiac surgery in Maine, New Hampshire, and Vermont. This group of institutions voluntarily reports outcomes on patients undergoing coronary bypass operations, valve operations, and PCI. At last report, more than 190,000 patients had been registered with this database. This database was originally founded as a regional prospective study to examine variations in outcome following CABG in this region. The initial report from this database in 1991 evaluated 3,055 patients undergoing isolated CABG operations. This study noted that crude, unadjusted mortality rates provided insufficient data to gauge performance. Although the study documented a range for in-hospital mortality from 3.1% to 6.3%, these regional data also suggested that differences observed in in-hospital mortality rate could not be explained solely by patient risk factors. Rather, the data suggested that differences in isolated CAB outcomes may have resulted from unmeasured differences in care.

This group then explored a regional strategy to learn “best practices” from each other. This strategy employed four components: regular feedback of outcomes data, efforts to determine causes of mortality, structured round-robin visits between organizations, and determinations of cause-specific mortality. This innovative sharing of information resulted in a subsequent reduction in the CAB mortality rate for the region by 24% over an 18-month period despite a higher risk population being operated on during this period.

In 2000, the group published data demonstrating 44% relative risk reduction over a 5-year period from 1992 to 1997 for aortic valve replacement and a 53% relative risk reduction for mitral valve replacement, potentially associated with the group’s quality improvement efforts. A randomized trial comparing neurocognitive outcomes from on-pump versus off-pump coronary bypass was published in 2007 demonstrating a lack of difference in this outcome. This group has over 100 peer-reviewed publications from the database covering a myriad of topics focused on risk factors and quality improvement. The NNE cardiovascular group continues to collect data and explore and try to alter risk factors for negative outcomes in cardiac surgery as well as PCI.

**Michigan Regional Collaborative Improvement Programs**

As we have learned from the New York state database review, public reporting of hospital and surgeon outcomes paradoxically does not negatively affect market share of poor performing programs. Taking that into consideration, regional collaborative programs like the one in Northern New England may be able to identify problem
areas and correct them to improve quality. The Michigan Society of Thoracic and Cardiovascular Surgeons (MSTCVS) began analyzing STS data for half the cardiac surgery programs in Michigan to implement a quality initiative in the late 1990s. Subsequently, Blue Cross/Blue Shield of Michigan (BC/BS), which covers 47% of the state’s population, began funding nine regional collaborative quality improvement programs in the mid-2000s, including a cardiac surgery program in 2006. The cardiac surgery collaborative was based on the pre-existing efforts of the MSTCVS. This program was to include all cardiac surgery programs in the state and BC/BS would provide funding for personnel and data collection. BC/BS also funded required quarterly meetings to review data. The program uses STS data registry with some additional variables and provides hospital and physician-specific outcomes data and statewide and national benchmark data to aid in local quality improvement. In the first 3 years following inception, this collaborative was able to identify significant variance relative to internal mammary artery use and prolonged ventilation and significantly improved both variables at outlier centers. The Michigan program is yet another example of a successful regional quality improvement program. What makes it unique is its private payer funding and collaboration that results in net benefit to the patients, hospitals, surgeons, and payer in the form of reduced costs.

Virginia Cardiac Surgery Quality Initiative

The Virginia Cardiac Surgery Quality Initiative (VCSQI) was formed in 1996 as a voluntary consortium of cardiac surgery programs and now includes 17 hospitals and 13 surgical groups that perform all of the cardiac surgeries in Virginia except for the Veterans Administration. The mission of this group is to improve clinical performance among all cardiac surgery programs by using outcomes analysis and process improvement. The database includes STS registry data (all hospitals report to the STS) and also links these cases to the costs as reported by the hospital. The meetings include physicians, nurses, administrators, data managers, and others to create a multidisciplinary atmosphere. As with other local collaborative, VCSQI has sought to identify outlying outcomes and review them to make improvement. Additionally, they have implemented several best practice initiatives based on their own data to reduce perioperative transfusion, atrial fibrillation, prolonged ventilation, and hyperglycemia. The unique combination of outcomes data with cost data has allowed VCSQI to estimate costs associated with complications and hence to estimate cost reduction by quality improvement. This has led to their pioneering efforts in pay for performance models and quality-based payments.

California Cardiac Surgery and Intervention Project

California first entered into public reporting in 1996 with the California CABG Mortality Reporting Program. Reporting was voluntary and many hospitals, perhaps preferentially those with suboptimal results, did not report data. Public reporting in California began from this but the data were too limited to make solid conclusions from. A law supported by the California Society of Thoracic Surgeons (CASTS) was passed in 2001 by the California State Senate to require public reporting of all surgical outcomes, beginning with CABG in 2003. The project was begun by the CASTS and the California Cardiac Surgery and Intervention Project (CCSIP) was formed to help enhance the database with a focus on quality improvement. The state uses STS data elements, with slight modifications and definitions, and analyzes the data and issues surgeon-specific risk updated mortality reports for CABG publically.

The first paper in 2005 compared California’s outcomes in CAGB and PCI with the well-established New York database. Surprisingly, CABG mortality was 33% higher in California and PCI mortality was double that of New York. However, programs performing >300 CABG per year had equivalent mortality to New York (2.45%). Excess mortality only occurred at the lower volume programs, and this relationship did not change with risk adjustment. The PCI mortality had no volume-outcome relationship.

A follow-up study was published in 2009 after several years of public reporting and CCSIP intervention. Total CABG volume decreased from 28,495 cases in 1997 to 15,520 cases in 2006. On the other hand, PCI volume increased from 38,098 to 53,703 in the same period. Even with the decrease in CABG volume, risk-adjusted mortality decreased from 4.7% to 2.1% for CABG and from 3.4% to 1.9% for PCI. Interestingly, combined rates of death, MI, or repeat revascularization were double in the PCI group. Additionally, the volume-outcome relationship was no longer statistically significant, though the trend still existed.

This suggests that quality improvement initiatives did alleviate the quality issues at some low volume centers. This is yet another example of successful quality intervention.

Massachusetts

As in many other states, Massachusetts cardiac surgeons and legislators began thinking about establishing a cardiac surgery database along with public reporting in the late 1990s. Massachusetts was somewhat unique in that there were only 11 cardiac surgery programs due to strict “determination of need” certification on the part of the state. However, community hospitals that had banded together strongly requested to be allowed to perform cardiac surgery, and it was this debate that accelerated the need for outcomes measurement and quality control. The cardiothoracic surgeons of Massachusetts succeeded in having the STS national cardiac database used as the acquisition tool for the data. The data are reported both to the STS NCD as well as Massachusetts Data Analysis Center (MDAC) to allow for state-specific report generation. It was decided that hospital-level public reporting would occur, whereas surgeon-specific data would be protected and analyzed privately.

Data collection began January 1, 2002 and the first report card was published October 19, 2004 demonstrating no significant differences among cardiac surgery programs in Massachusetts. In the subsequent years, this database has spawned multiple clinical research projects and resulting publications identifying effectiveness of specific interventions and risk factors for poor outcomes.

Veterans Administration Database

The Cardiac Surgery Consultants Committee was organized under a congressional mandate to review the surgical results of the 43 VA medical centers performing cardiac surgery beginning in 1972. In 1987, the committee acknowledged the limitations of using only raw unadjusted mortality data to determine whether the appropriate level of surgical care was being delivered. This group sought and received authorization and funding from the VA to incorporate patient risk factors for the assessment of cardiac surgical results. Dr. Karl Hammermeister, one of the members of the committee, had experience with risk adjustment for cardiac surgery through his involvement with the Coronary Artery Surgery Study (CASS). He, therefore, took this knowledge...
to the VA to help develop the risk-adjusted methodology for measuring outcomes in cardiac surgery for the purpose of quality improvement. He worked with Dr. Grover to initiate this in the Veterans Administration (VA) Cardiac Surgery Database, the first national risk-adjusted cardiac surgery database. A similar initiative was undertaken 2 years later by Dr. Shukri Khuri in the area of general surgery and other surgical subspecialties with the development of the VA National Surgery Quality Improvement Program (NSQIP).

The initial report of the VA’s National Risk Adjusted Cardiac Database occurred at the STS meeting in 1989. The VA Cardiac Surgery Database vastly improved in 1991, when 44 nurse data managers were assigned to the hospitals performing cardiac surgery to collect data for both cardiac and general surgery programs. This allowed for virtually 99.9% complete capture of data points, a crucial factor in having valid data. Data entry from each surgical program is mandatory. The data were distributed back to the local hospitals, including the cardiac surgical team, cardiologists, and hospital administrators on a 6-monthly basis, with the observed and expected mortality rates for each of hospital blinded expected except for one’s own hospital. Over a 20-year period, there has been a significant reduction in risk-adjusted mortality for VA cardiac surgery (Fig. 38.1). The expected mortality rate for each cardiac surgery program is computed by calculating the expected probability of the 30-day mortality for each patient and then averaging the probabilities for all patients having cardiac surgery at the given hospital. A ratio of the observed mortality rate to the expected mortality rate is then calculated. This analysis also includes major morbidities that are also risk adjusted.

This information is now reviewed by the VA Surgical Quality Improvement Program (VASQIP) Executive Committee and the Cardiothoracic Surgery Advisory Board on a quarterly basis. VA cardiac surgery is one of numerous surgical subspecialties that are monitored by the VA and the VASQIP Executive Committee and each subspecialty has its own Surgery Advisory Board (SAB). It is noteworthy that 59 publications have occurred from the cardiac surgical database since its inception. One of the most important studies was the prospective randomized ROOBY Trial, which demonstrated better 1 year outcomes with on-pump coronary bypass as compared with off-pump.

Within the VA system, the risk-adjusted surgical results are used for two purposes—to prompt oversight review by the committees and the individual cardiac surgery programs and feedback to the individual cardiac surgery programs to provide comparison data with the other VA cardiac surgical programs to stimulate their attention to quality improvement.

**History of the Development of the Society of Thoracic Surgeons National Database**

The STS began initial meetings to develop databases in 1988, including adult cardiac surgery, congenital heart surgery, and general thoracic surgery. The initial emphasis was in the adult cardiac surgery area because of the public release of hospital CABG data in 1986 by HCFA (Healthcare Financing Administration, now CMS) and subsequently in New York State by the New York State Cardiac Surgery Database. By 1994, over 1,500 surgeons operating in 706 hospitals in 49 states had entered more than 500,000 patients into the database with a decrease in coronary bypass operative mortality from 3.7% to 3.1%. In 1996, efforts were made to expand the goals of the STS database, leading to the hiring of the first national database coordinator, Mary Eiken. In 1999, a contract with Duke Clinical Research Institute (DCRI) was signed for warehousing and analysis of the data and multiple software vendors were contracted after approval for data entry and transmission of data to DCRI. This marked a new era for the STS Databases and the STS...
Adult Cardiac Database progressed in its maturity and the sophistication of its analysis and research, and much progress was made in the development of more mature general thoracic and congenital cardiac databases. In 2004, Cynthia Shewan was recruited to be the Staff Director of Quality Research and Patient Safety. The STS Databases are now the largest registries of clinical cardiothoracic surgery data in existence. The STS Database is now chaired by Dr. David Shahian and it has taken on many functions. However, the highest priority remains quality improvement in the care of cardiothoracic surgical patients.

**Society of Thoracic Surgeons Adult Cardiac Surgery Database**

The STS Adult Cardiac Surgery Database now has 1,067 groups participating, which is well over 90% penetration of all cardiac surgical programs in the United States. It contains over 4.8 million records including 1.8 million isolated CABG records from 2000 to 2011. Data auditing was put in place in 2009 and an increasing number of sites are audited each year, forty in the past year with 96% overall agreement. Performance measures have been endorsed by the National Quality Forum and the AQA are used by many hospital systems and payor systems in their quality programs. The data are now distributed back to cardiac surgery programs, their hospitals, and cardiologists on a quarterly basis using a three-star composite score, with three stars outstanding, two stars satisfactory, and one star needing improvement (Fig. 38.2). The details of this were discussed earlier in the chapter.

Over the past two decades, as in the VA program, there have been significant reductions in risk-adjusted operative mortality for cardiac surgery patients (approximately 60%) as demonstrated by the reduction of coronary bypass grafting operative mortality in the decades of the 1990s and the first decade of the 21st century (Fig. 38.3A and 38.3B). The coronary bypass data are now being publically reported through the Consumers Union Website as well as the STS’ Web site. Currently, approximately 40% of groups in the United States are voluntarily reporting their data publically and this percentage continues to modestly increase each year. Risk models are updated every several years and new ones are created with the adult cardiac surgery database with risk models for CABG only, aortic and mitral valves only, and CABG/valve procedures. Plans are also underway for publically reporting outcomes for other adult cardiac procedures.

**The Society of Thoracic Surgeons General Thoracic Surgery Database**

The General Thoracic Surgery Database now receives data from over 229 groups (785 surgeons) participating with 312,000 operations entered since 2002. The data are harvested twice a year, with the spring 2012 harvest being the fourteenth. Data are distributed back to the surgeons and their local hospitals. The first risk models have been completed for prolonged length of stay for lobectomy and for morbidity and mortality for esophagectomy. Audits were initiated in 2010 and 10 sites were audited in 2011 and will increase to 10% of sites in 2012. Seven general thoracic measures have been endorsed by the National Quality Forum. Eight publications have been published from this database since 2008.

**The Society of Thoracic Surgeons Congenital Cardiac Database**

There are currently 103 participants using the STS Congenital Cardiac Surgery Database, from an estimated 125 U.S. pediatric cardiac surgery programs, with 213,416 total operations in the database. The STS-EACTS scores are utilized for risk adjustment. Audits began in 2007 with five occurring in 2011 and 10% of sites for 2013. The 20th harvest took place in the spring of 2012. Eighteen publications have come from this database since 1995, nine in the last 3 years, including a paper analyzing the complex relationships between surgical case volumes and mortality (Fig. 38.3B).

**RECENT ADVANCES AND PROJECTS**

There has been major activity in linking the STS Database with other databases, both administrative and clinical, including CMS, the American College of Cardiology (ACC) interventional database, ACC pediatric cardiac database, the National Death Index, the Society Security Death Index, the Pediatric Cardiac Intensive Care Society database, the Extracorporeal Life Support Organization registry, hospital billing systems, and private payor systems. Through these linkages, it is possible to follow long-term outcomes as well as to obtain cost data, which can then be used to evaluate the early and late value of the procedures that should be useful for value-based purchasing of health care, which is currently being initiated. Research using the STS databases has resulted in 121 peer-reviewed publications.

Because of the increasing interest and activity in research, an STS Research Center was established in 2012, with Fred Edwards serving as the Director of the Center and Cynthia Shewan as the Director of Research and Scientific Affairs. DeLaine Schmitz was hired at this time as Director of Quality.

The STS also has received numerous grants from external funding sources utilizing the databases. The most prominent grant thus far is the NIH Go Grant as part of the President’s Stimulus Program, which funded the STS and the ACC and DCRI to perform a comparative effectiveness study of PCI versus CABG linking the STS and ACC databases with the CMS administrative database (ASCERT Trial). This study was published recently in the New England Journal of Medicine and there are several sub-studies of that data now underway.

This study demonstrated that during the first year, there was a lower risk of mortality in the PCI group, but after 1 year there was progressively favorable survival with coronary bypass as compared with PCI for two- and three- vessel coronary artery diseases (Fig. 38.4). The study like any other retrospective observational study may have unknown and/or uncaptured confounding variables but has demonstrated results similar to the New York State Database observational studies and the prospective randomized Syntax Trial.

**HEALTH POLICY AND COLLABORATION WITH THE GOVERNMENT AND OTHER ENTITIES**

Because of the high penetration of the STS Databases in practicing programs and their reputation for accuracy and sound scientific methodology, these databases have been very effective in building strong relationships between the cardiothoracic surgical community, health policy groups, and the government including the legislative and executive branches, and regulatory agencies. Recently, a landmark decision has been made by the FDA and CMS to invite the STS and the American College of Cardiology to be involved with the criteria and measurement for the efficacy and safety of transcatheter aortic valve replacements. Working with FDA and CMS, criteria were developed to determine which patients are initially eligible for these valves, what the program standards are for both cardiology and cardiac surgery, and very importantly, establishing that data will be captured on all patients receiving these valves in

¹*, participant performance is significantly lower than the STS mean based on 99% Bayesian probability; **, participant performance is not significantly different than the STS mean based on 99% Bayesian probability; ***, participant performance is significantly higher than the STS mean based on 99% Bayesian probability.
²Includes reoperations, renal failure, deep sternal wound infection, prolonged ventilation, and CVA.
³Excludes patients with prior CABG surgery.
⁴Includes preoperative beta blockade, discharge beta blockade, discharge anti-lipids, and discharge anti-platelets. Excludes v2.61 contraindicated/not indicated records.

Fig. 38.2. This is an example of the Society of Thoracic Surgeons reports that individual cardiac surgical groups receive on their performance and includes the three-star rating with three stars being above average, two stars average, and one star below average.
Fig. 38.3. These Society of Thoracic Surgeons graphs demonstrate an approximately 60% reduction in the observed to expected mortality rates for coronary artery bypass patients for the decades of the 1990s (A) and for the first 5 years of the 21st century (<0.0001) (B). (From: Grover FL. The bright future of cardiothoracic surgery in the era of changing health care delivery: an update. Ann Thorac Surg 2008;85:8-24, doi:10.1016/j.athoracsur.2007.10.100, with permission.)

Fig. 38.4. This is a graph of early and late mortality with inverse probability weighting for patients receiving percutaneous coronary intervention versus coronary artery bypass grafting for two- and three-vessel coronary artery disease. You will note that after the first year, survival is progressively greater with the coronary bypass group with a 21% less relative risk of death. CABG, coronary artery bypass grafting; PCI, percutaneous coronary intervention. (Modified from Weintraub WS, Grau-Sepulveda MV, et al. Comparative effectiveness of revascularization strategies. N Engl J Med 2012;366(16):1467-1475, doi:10.1056/NEJMOA1110717.)
the United States. This database is being housed in the Duke Clinical Research Institute, with the data being collected through the ACC on the front end and the STS and ACC along with DCRI participating in the analysis and reporting of the data to the FDA, CMS, and industry and participating surgeons and cardiologists and their hospitals. This is extremely important because it involves physicians participating in the process of the "rational dispersion" of new technology. Hopefully, this process will lead to the development of appropriate use criteria and minimizing inappropriate use of these valves until data are out showing not only their short-term but also their long-term efficacy. This relationship between the above organizations will hopefully lead to similar applications for other new cardithoracic and cardiology technologies.

As another example of collaboration with the government and other groups, the STS and DCRI have recently been asked by CMS to work with the Yale Group to develop a method of measuring and evaluating hospital readmission rates following CABG using STS clinical data and Yale administrative data (obtained from CMS).

SUMMARY

The cardiothoracic surgery, cardiology, and general surgery specialties have set an example for other physicians to fulfill their professional obligations to society by developing robust quality improvement programs based on risk-adjusted clinical data. These databases have given our cardithoracic specialty credibility with Congress, the Executive Branch, including CMS and the FDA, payors, purchasers, and the major quality improvement organizations, such as the National Quality Forum. The databases offer real-world research potential and the opportunity for prospective randomized trials as well. In addition, they offer opportunities for short- and long-term comparative effectiveness studies of various treatments and procedures. They are and will be utilized more in measuring efficiency and value going forward. They can be used for public reporting so that our specialties are seen by the public, the health policy groups, the government, and the purchasers as being transparent, which is very important in our culture. They have also been helpful in reimbursement negotiations demonstrating not only the quality and services rendered, but the workload involved. They are also a valuable tool for recertification and maintenance of certification for all physicians. Finally, databases are emerging as a tool that can be utilized
to develop specialty society–government collaboration with organizations such as CMS and FDA and with industry in partnering in device monitoring and the dispersion of new technology.

The database acquisition of risk-adjusted clinical data through professional societies databases including the STS, the American College of Cardiology, the American College of Surgeons, and the VA databases has been integral in improving patient care by allowing each surgeon and physician to compare their results with national and regional peer groups to identify areas for improvement.

SUGGESTED READINGS

Dr. Grover and his colleagues have true expertise in the field of databases and this is the reason I asked them to do this chapter. Very few developments have had more impact on the practice of cardiac surgery than those of national databases. This chapter goes through the history of the STS database, which is the measurement of results for our entire field. I think new practitioners need to understand that they will be judged by the results of databases and they need to carefully measure their own outcomes. In addition, they really have to be cognizant of the administrative databases that included billing data. These are public record and we truly have to understand the nuances of what they mean and do. They are not perfectly accurate yet they are relevant.

Though databases have many positive aspects, there is the issue discussed by the authors whether cases are turned down to improve results. Certainly, every experienced practitioner knows that they can determine their own mortality for coronary artery bypass grafting. There have been studies that the authors have quoted reviewing whether in fact the turn down rate is higher in places where there is public reporting. Eventually, there needs to be some system that studies both patients who are operated on the patients that are treated at a given institution. One must know numerator and denominator. However, this is not possible at this point.

ILK
Prevention of Neurologic Injury after Coronary Artery Bypass

George J. Arnaoutakis and William A. Baumgartner

INTRODUCTION

Coronary artery bypass grafting (CABG) increases long-term survival compared with medical therapy for patients with significant coronary artery disease. Improvements in anesthesia, surgical technique, and myocardial protection have led to improved operative mortality rates. Despite these improvements, neurologic injury remains a significant risk for patients undergoing CABG. Aside from being a leading cause of morbidity in CABG patients, neurologic sequelae also account for escalating medical costs in the form of increased length of hospital stay and subsequent rehabilitation.

The spectrum of neurologic injury ranges from clinical stroke to more prevalent, yet subtle neurocognitive changes. According to a recent Society of Thoracic Surgeons (STS) report clinically evident stroke occurs in 1.4% of patients undergoing CABG and is associated with significantly worse early and long-term survival after CABG. Delirium occurs in up to 10% of patients >65 years of age and is also associated with worse long-term mortality. Other early postoperative neurocognitive abnormalities occur in up to 60% of patients and manifest as mild deficits in memory, attention, concentration, and language. Many of these subtle neurocognitive changes are transient, however, and are known to resolve at 3 months post-CABG. The three main etiologic factors involved in neurologic injury are atherosclerotic emboli, cerebral hypoperfusion, and generalized perioperative inflammation. Identifying the mechanism of injury and potentially modifiable risk factors for unfavorable neurologic outcomes is an active area of research, and many potential neuroprotective strategies have emerged.

Preoperative comorbidities predisposing to neurologic complications after cardiac surgery include advanced age, prior neurologic events, hypertension, diabetes, renal failure, atrial fibrillation, peripheral vascular disease, and carotid stenosis. These risk factors identify individuals likely to have diffuse cerebrovascular disease, impaired cerebral blood flow (CBF), or increased susceptibility to thromboembolic events. To screen for patients with asymptomatic carotid stenosis, carotid duplex ultrasonography should be performed in patients with audible bruits or in elderly patients at high risk for cerebrovascular disease.

Studies have also identified intraoperative predictors for perioperative neurologic events. These independent risk factors include the presence of significant aortic arch atherosclerosis, longer duration of cardiopulmonary bypass (CPB), and CABG with concomitant carotid endarterectomy. The preoperative recognition and assessment of risk factors is an important step in reducing the morbidity and mortality associated with perioperative neurologic injury.

MECHANISM OF NEUROLOGIC INJURY

The development of potential therapeutic strategies depends on our understanding of the mechanism of neuronal cell injury following cardiac surgery. “Glutamate excitotoxicity” is a major mechanism of neuronal injury. Glutamate is the major excitatory amino acid neurotransmitter in the central nervous system (CNS) and can cause neuronal hyperactivity and death during periods of metabolic stress such as hypoxia or ischemia (Fig. 39.1). Glutamate triggers a cascade of events via binding to an N-methyl-D-aspartate (NMDA) receptor, ultimately resulting in neuronal necrosis or apoptosis. Histologically, the brain regions most significantly affected are those in which NMDA receptors are prominent: the hippocampus, cerebellum, and basal ganglia. Pharmacologic blockade of this receptor also confers some degree of neurologic protection in animal models, thus reinforcing this mechanism of injury.

Nitric oxide (NO) is a ubiquitous molecule that also acts as a neurotoxin. Induction of neuronal nitric oxide synthase (nNOS) via a hypoxic/ischemic insult leads to diffuse NO formation in the brain. NO and its metabolite peroxynitrite impart toxic effects on the neuronal mitochondria, resulting in free radical proliferation and DNA fragmentation (Fig. 39.2). Mitochondrial energy failure is considered to play a central role in neuronal cell death. Investigations using a canine model of hypothermic circulatory arrest (HCA) showed that inhibition of nNOS results in decreased NO production and superior neurologic function compared with untreated HCA canines. These studies demonstrated that pharmacologic intervention at specific points in the injury cascade might potentially mitigate the neurologic deficits that can result from cardiac surgery.

CEREBRAL PROTECTION TECHNIQUES

Minimizing the Systemic Inflammatory State

CPB is associated with an intense inflammatory response due to contact of blood with the artificial bypass surfaces, conversion to laminar, nonpulsatile flow, and leukocyte and endothelial cell activation following ischemia/reperfusion. The systemic inflammatory response is characterized by activation of the complement, fibrinolytic, and cytokine cascades. Complement activation occurs immediately after the blood comes into contact with the foreign surfaces of the bypass circuit. This leads to leukocyte activation and increased inflammatory cytokine production, such as interleukin-6 and tumor necrosis factor. The leukocyte–endothelial cell interactions result in microvascular occlusion and end-organ ischemia. This inflammatory response is the suspected mechanism underlying the global cerebral edema seen on post-CPB magnetic resonance imaging (MRI).
Many therapeutic strategies have been used in an attempt to mitigate the CPB-induced inflammation. These include both pharmacologic and mechanical therapeutic modalities. Corticosteroids have been shown to reduce CPB-induced inflammation by decreasing complement activation and levels of circulating cytokines. However, a large Cochrane Database review of over 3,600 patients revealed that the routine use of preoperative corticosteroids in adults did not confer any clinical benefit, including no improvement in neurologic complications. The serine protease inhibitor aprotinin was shown to reduce the inflammatory response post-CPB and possibly decrease postoperative stroke risk. However, due to increased risk of fatal myocardial infarction and renal failure, this drug is no longer available. Experimental evidence in animal models suggests decreased post-CPB inflammatory response in subjects pretreated with statin therapy; however, a large cohort study failed to demonstrate a clinical benefit in neurologic outcomes.

Mechanical strategies to reduce the release of proinflammatory cytokines include leukocyte and hemocompensation filters, which wash the cells before returning them to the bypass circuit. However, despite several studies documenting reductions in measured cytokine concentrations, significant clinical benefit has not been shown. In an attempt to increase the biocompatibility of CPB, heparin-coated circuits also reduce complement activation, proinflammatory cytokine levels, and neutrophil adhesion. A prospective, randomized trial of heparin-coated circuits demonstrated a significant improvement in postoperative neurophysiologic tests as compared with conventional circuits.

**Maintenance of Cerebral Perfusion**

Under normal physiologic conditions, cerebral autoregulation maintains a constant CBF over a wide range of systemic arterial pressures (50 to 120 mmHg). Below 50 mmHg, cerebral oxygen delivery (\(CDO_2\)) becomes pressure-dependent. This can be compensated for by an increase in cerebral oxygen extraction. Therefore, \(CDO_2\) remains relatively constant even at systemic pressures as low as 30 mmHg during moderate hypothermia. However, because of the burden of comorbidities prevalent in CABG patients, including hypertension, diabetes, and cerebrovascular disease, the ischemic tolerance and autoregulatory capacity of the brain are diminished. For this reason, higher minimal perfusion pressures may be required to support adequate cerebral oxygenation. Thus, flow rates during CPB are adjusted to preserve end-organ and cerebral perfusion above an ischemic threshold.

However, the watershed areas of the brain still remain at greatest risk for neurologic injury. A prospective, randomized trial of 248 elective CABG patients showed that those maintained at lower perfusion pressures (50 to 60 mmHg) had significantly higher mortality and stroke rates than those maintained at a higher perfusion pressure (80 to 100 mmHg). This study demonstrated that maintaining patients on CPB at a higher perfusion pressure was technically safe and effectively improved outcomes after cardiac surgery. The current perfusion practices, which err on the side of higher perfusion pressures, result in excellent outcomes in the vast majority of patients, and there is little evidence to suggest that altering these practices will have a positive influence on CBF.
Emboli are spherical or elongated aggregates of red cells, platelets, and fibrin, which may have a central core of debris. The platelet-fibrin aggregates are composed of fibrin monomers and are thought to extend through small vascular openings. The platelet-fibrin aggregates are highly viscous and may have a central core of debris. The aorta is the most common source of emboli, and the majority of emboli are composed of aortic material and cerebral embolization. A recent study showed that 1.5% of patients undergoing CABG surgery developed postoperative stroke, and the use of an automated aortic embolization filter significantly reduced the incidence of stroke.

There are three main types of emboli: platelet-fibrin aggregates, aortic material, and cerebral embolization. Platelet-fibrin aggregates are composed of fibrin monomers and platelets, and they are highly viscous. Aortic material emboli are composed of aortic debris and are highly viscous. Cerebral emboli are composed of aortic debris and are highly viscous.

Embolization Reduction

There are three main types of embolic phenomena that may occur during cardiac surgery and result in postoperative neurologic dysfunction: particulate, gaseous, and lipid embolization. Perhaps, the most significant of these is the particulate emboli resulting from atheromatous debris present in the diseased aorta and great vessels. The platelet-fibrin aggregates and debris generated by the CPB circuit itself also have a causative role. To limit particulate embolization, surgical manipulation of the heart and great vessels must be minimized and care should be taken in the placement of cannulae and clamps on atherosclerotic vessels. In addition to intraoperative palpation, transesophageal echocardiography (TEE) and epiaortic ultrasonography are commonly used to assess the degree of aortic atherosclerosis and to identify more favorable areas for cannulation and clamping. In a recent study, patients undergoing epiaortic scanning showed a lower incidence of cognitive dysfunction than patients evaluated only with aortic palpation.

Cross-clamping of the atherosclerotic aorta can result in dislodging of plaque material and cerebral embolization. A number of recent studies evaluated the use of a single-clamp technique (SCT) versus a double-clamp technique (DCT) for cerebral protection during CABG. In the DCT, the cross-clamp is removed before the proximal aortic anastomoses, which are then performed using a partial occluding clamp. This technique reduces the overall CPB and myocardial ischemic time but results in increased aortic manipulation and risk of embolization. A retrospective study of 189 SCT versus 272 DCT patients showed DCT to be an independent risk factor for neurologic injury on multivariate analysis. A recent prospective trial randomized 268 patients undergoing CABG to either SCT or DCT. The DCT group included two patients (1.5%) with a postoperative stroke and two patients (1.5%) with postoperative confusion. The SCT patients demonstrated improved cerebral protection, with no postoperative neurologic complications, and no adverse effect on myocardial protection or postoperative outcome.

Novel alternatives have also evolved to decrease aortic manipulation and subsequent embolic risk. Endovascular balloon occlusion of the ascending aorta has been described as one method for avoiding the potential injury caused by cross-clamping of the aorta. Intra-aortic filtration systems (Emboli-X; Emboli-X, Inc., Mountain View, CA) have also been developed for deployment before cross-clamp release in an effort to reduce the embolic burden. A large, randomized trial of >1,200 patients demonstrated the filtration system to be both safe and effective with a filter embolic capture rate of 96.8%. However, postoperative event rates including mortality, stroke, transient ischemic attack, and renal insufficiency showed no significant differences between the control and filter arms of the study. When specifically examining a high-risk subgroup, there did appear to be a clinical benefit with respect to a composite outcome of mortality or major morbidity. Aortic manipulation can also be minimized with the use of automated aortic connectors for the construction of sutureless proximal saphenous vein graft-aortic anastomoses. Again, a recent prospective trial of 77 primary CABG patients randomized to either the automated anastomotic device or conventional handsewn anastomosis demonstrated no significant differences in neurocognitive deficits, stroke, or mortality.

Cerebral air embolization is another potential source of postoperative neurologic dysfunction. Air can be entrained into the heart from the surgical field. However, this is more pertinent to open-chambered procedures such as valve operations than with routine CABG. Flooding the surgical field with CO₂ is one method used to decrease the embolic burden. The CPB circuit can introduce air into the patient, but this is theoretically avoided by the venous reservoir design and arterial line filter. A dynamic bubble trap has been used to reduce gaseous microemboli, and in a prospective study was found to improve neuropsychological function at 3 months postoperatively. The number of perfusionist interventions, defined as the administration of drugs or the injection of blood into the venous reservoir, has also been correlated with the incidence of air microemboli. A prospective study of 83 CABG patients demonstrated that those with increased perfusionist interventions, and therefore increased gaseous microemboli, had significantly worse performance on neurocognitive testing. This study further implies the CPB circuit as a potential source of clinically significant microemboli. TEE is routinely used to assess the amount of intracardiac air and can assist in de-airing procedures.

Fat embolization into the cerebral circulation is a common occurrence due to aspiration of mediastinal and cardiac fat into the cardiotomy suction and CPB circuit. This lipid material is often small and deformable, and so can easily pass through arterial line filters. Lipid emboli in the cerebral circulation are an extremely common occurrence in postcardiac surgery patients, as determined postmortem. These emboli are associated with an upregulation of inflammatory cytokines in the brain, which may result in the systemic inflammatory response seen in some patients. Therefore, the current practice at our institution is to avoid the use of cardiotomy suction to prevent the return of lipid debris to the pump. Cell-saver or blood-salvage devices, however, can decrease the amount of particulate or lipid debris returned to the CPB circuit. When comparing cell-saver suction to standard cardiotomy suction, in a randomized trial of 226 patients, cell-saver was associated with less cognitive dysfunction. The main drawback to cell-saver devices is the washing away of platelet and coagulation factors that also occurs. Further technological refinements may circumvent this issue in the future.

Temperature Management

The issue of hypothermic versus normothermic CPB is an ongoing matter of debate. The potential benefit of hypothermic CPB is a decreased cerebral metabolic rate, which has been shown to decrease the neuronal injury associated with ischemia. Mild hypothermia also allows for lower flow rates, which can lower the risk of embolization. This risk, however, is greatest during aortic cannulation, cross-clamping and unclamping, and initiation of CPB. Unfortunately, the brain remains normothermic during these critical time periods due to the timing of hypothermia after the onset of CPB. In addition, hypothermia requires rewarming, which lengthens CPB and overall operative time. The rewarming process also harbors some potential to cause moderate hyperthermia if performed too rapidly, which has been associated with worsened neurologic outcomes. It is therefore important that during the rewarming phase the bladder temperature does not exceed 37°C to 37.5°C. Studies examining the effect of hypothermic versus normothermic CPB have produced conflicting results. Some studies suggest a decreased stroke rate and improved neuropsychological outcomes associated with hypothermic CPB, whereas others report no difference in neurologic complications. Overall, common practice is to induce a mild state of
hypothesis (32°C to 34°C), which is generally protective of all organs during CPB.

**Acid–Base Management**

The increased solubility of carbon dioxide in blood at lower temperatures has resulted in two different methods of acid–base management during hypothermic CPB. The pH-stat management technique uses a temperature-corrected arterial blood gas and maintains the pH at 7.40. This technique can result in a loss of cerebral autoregulation and an increased risk of neurologic injury. The α-stat management technique, however, does not use temperature-corrected arterial blood gases and therefore maintains the autoregulation of CBF. Studies comparing these two management strategies have had varied results. Some animal studies have advocated the use of the pH-stat method due to improved functional outcomes and less severe neuronal injury. However, other studies report a higher incidence of postoperative neurologic dysfunction in patients treated with the pH-stat method. This may be due to increased CBF associated with the loss of autoregulation, which can lead to an increased delivery of microemboli to the cerebral circulation. Despite conflicting opinions, the majority of adult practices today utilize the α-stat management technique.

**Pharmacologic Intervention**

Many different pharmacologic agents have been explored for their potential neuroprotective effects in both experimental and clinical models. There are no approved therapies for the specific prevention of CABG-associated neurologic events. However, a multi-institutional prospective observational study revealed that early initiation of aspirin in the post-CABG period improved numerous outcomes, including a 50% reduction in stroke rates.

In addition, various anesthetic agents have been used in conjunction with electroencephalography in an effort to suppress cerebral oxygen metabolism. Anti-inflammatory agents have been tried to prevent the adverse inflammatory sequelae of cerebral ischemia. However, the limited success observed with these agents may not be due to a direct neuroprotective effect, but rather by an indirect effect on cerebral emboli. As the mechanism of injury is further elucidated, the potential targets for intervention continue to increase. Our understanding of glutamate excitotoxicity with increased NO production and neuronal cell death has led to the rational exploration of glutamate-receptor blockers and NO synthase inhibitors. These agents have shown beneficial neurologic effects in our experimental canine model of HCA. HCA is considered to carry the greatest risk of neurologic injury and is therefore a practical model for pharmacologic investigations.

The inhibition of mitochondrial energy failure is another strategy for preventing the ischemia-induced neuronal injury in our canine HCA model. Ischemic preconditioning (IPC) is a paradoxical form of protection against lethal ischemia by exposure to brief episodes of ischemia prior to the primary insult. Although initially described in cardiac myocytes, a similar mechanism was also found in neurons and may confer mitochondrial protection. One potential mechanism of IPC relies on the opening of ATP-dependent K⁺ channels on the inner mitochondrial membrane. This effect can be achieved pharmacologically by using a variety of different agents. Diazoxide, an antihypertensive medication no longer in clinical use, is one such ATP-dependent K⁺-channel agonist. Pretreatment with diazoxide before neurologic insult has been correlated with improved functional outcomes and histopathology. This has been further substantiated by the antagonistic effect of glibenclamide, an ATP-dependent, K⁺-channel antagonist. In the current age of molecular-targeted drug design, further success in pharmacologic neuroprotection will become increasingly feasible as our mechanistic understanding continues to improve. There is also evidence in our canine model that the anticonvulsant medication valproic acid may offer neuroprotection; however, concerns regarding metabolic acidosis have limited broader application in the clinical setting.

**Hematocrit Management on Cardiopulmonary Bypass**

Hemodilutional anemia has been used during hypothermic CPB to reduce blood viscosity to allow maintenance of baseline CBF. This technique is perceived to reduce the risks of adverse outcomes due to arterial hypertension such as aortic dissection and collateral blood flow to the coronary arteries during cross-clamping of the aorta. Although a goal hematocrit level of approximately 21% was traditionally common practice, multiple recent studies have contradicted the appropriateness of this technique. In a randomized trial of 147 infants, Jonas and colleagues randomly assigned patients to a lower hematocrit strategy (21.5%) or a higher hematocrit strategy (27.8%) during hypothermic CPB. The lower hematocrit group had worse perioperative outcomes with significantly lower scores on the Psychomotor Development Index at 1 year of age. Another prospective observational study of 10,000 patients found that each 1% decrease in nadir hematocrit on CPB was independently associated with a 10% increase in the odds of postoperative stroke. At our institution, we similarly observed an independent association between low post-CPB hemoglobin levels and increased stroke risk. These studies suggest that inadequate oxygen delivery due to anemia may be the mechanism of cerebral injury. While adverse neurologic outcomes have been observed with low hematocrit levels on CPB, prospective randomized studies specifically addressing this issue are needed to better guide the optimal target hematocrit during CABG surgery.

**Glucose Control**

Disruption of cerebral energy metabolism plays a causative role in the neurologic injury that occurs following cerebral ischemia. Episodes of brain ischemia initiate anaerobic glycolysis with subsequent intracellular lactic acidosis, which causes cellular toxicity. An increase in blood glucose concentration at the time of ischemia provides more substrate for anaerobic metabolism with exacerbation of the acidosis. Studies show that hyperglycemia at the onset of cerebral ischemia worsens postsischemic neurologic function and histopathologic injury. In a primate model of complete cerebral ischemia, animals receiving a glucose infusion immediately before ischemic insult had significantly worse neurologic function at 96 hours than control animals receiving a crystalloid infusion. Large clinical studies have shown that diabetic CABG patients with poorly controlled perioperative hyperglycemia had higher rates of sternal wound infections and worse long-term survival. However, because of concern of serious hypoglycemia, there has been a paradigm shift away from strict glycemic control (90 to 120 mg/dl) toward more moderate glycemic control (120 to 180 mg/dl) in CABG patients. The appropriate intraoperative management of hyperglycemia in patients undergoing CABG continues to evolve, but currently most centers strive to maintain glucose levels in the 120 to 180 mg/dl range, in concert with current STS recommendations.
Intraoperative Cerebral Monitoring

Intraoperative neurophysiologic monitoring reduces the incidence of neurologic complications after CPB. Several different modalities exist, including near-infrared cerebral oximetry, jugular bulb oximetry, EEG, somatosensory-evoked potentials (SEPs), and transcranial Doppler (TCD) ultrasound. These multimodality techniques can help detect cerebral hyperperfusion and impaired oxygenation, which contribute to brain injury during cardiac surgery. Cerebral oximetry is a simple method of measuring cerebral oxygenation. The level of cerebral oxygenated hemoglobin has been shown to correlate with high-energy phosphates and can predict histologic brain injury in an animal model. In addition, near-infrared spectroscopy can be used to continuously monitor CBF autoregulation in CABG patients. Real-time assessment of cerebral perfusion autoregulation may be useful in tailoring hemodynamic goals to an individual patient, thereby minimizing injurious hypotension during CPB.

Jugular bulb oximetry provides similar information regarding oxygen imbalance. However, it is more invasive due to the need for jugular vein cannulation. EEG and SEP monitoring have also been used as measures of cerebral metabolic activity. EEG silence and the disappearance of SEPs can be used as markers of adequate cerebral protection and can potentially shorten the cooling period during CPB. These two techniques, however, are more commonly utilized in patients undergoing HCA. TCD ultrasound can detect sudden changes in either blood flow or vascular resistance, as well as aid in the identification of embolic phenomena. In addition to detecting abnormalities, these modalities can be used to make adjustments in perfusion, oxygenation, or anesthetic administration. When used effectively, intraoperative cerebral monitoring shortens hospital stay, decreases costs, and prevents neurologic complications.

Off-Pump Coronary Artery Bypass

With the development of cardiac immobilization techniques that enable complete revascularization of the beating heart, there was speculation that by avoiding use of CPB off-pump CAB (OPCAB) would reduce neurologic complications. CPB is associated with an intense inflammatory response secondary to the conversion to laminar flow, blood contact with the artificial bypass surface, cold cardiac ischemia, and reperfusion. In addition, other CPB-related factors such as hemodilution and aortic cross-clamping play a significant role in postoperative neurologic dysfunction. OPCAB has the potential advantage of avoiding the inflammatory response and micro/macromemboli that may result from the CPB circuit and manipulation of the atheromatous aorta. Some retrospective studies suggest a decreased early stroke rate with OPCAB, although delayed stroke rates were equivalent. However, numerous prospective, randomized studies have failed to demonstrate significant neurologic benefit over CABG with traditional CPB. Although OPCAB may offer some theoretical advantages, its ability to reduce the risk of neurologic complications is presently unproven. The growing recognition that OPCAB does not appear to improve neurologic outcomes has led to a shift in focus toward patient-related factors, such as arteriosclerotic burden, that predispose patients to neurologic morbidity.

ASSESSING NEUROLOGIC INJURY

Neuropsychological Testing

Traditional studies in the area of postcardiac surgery neurologic outcomes focused on clinically obvious neurologic and psychological dysfunction such as stroke, disorientation, and depression. However, with more widespread use of neuropsychometric testing, more subtle injury patterns can be observed. This testing typically includes measures of language, memory, attention, concentration, and psychomotor performance. In a prospective study of 127 patients undergoing CABG, patients were given a battery of cognitive tests preoperatively, 1 month postoperatively, and 1 year postoperatively. This study established that the incidence of cognitive decline varies among the different domains of cortical function tested. More importantly, however, these patients must be followed longitudinally because initial deficits may eventually show either improvement or further decline. We recently performed a prospective study examining the longitudinal neuropsychological performance of CABG patients versus nonsurgical controls with coronary artery disease. The cognitive testing results at 3 months and 1 year after baseline examination were comparable between the two groups, suggesting that the cognitive decline during the early post-CABG period may be transient and reversible. Therefore, any long-term cognitive dysfunction may be related to age and other comorbidities such as vascular dementia, as opposed to directly attributable to CPB exposure. With further research into neurobehavioral assessment techniques, it will be possible to evaluate the effectiveness of surgical and pharmacologic strategies for mitigating neurologic injury after CABG surgery.

Molecular Markers

Various proteins released by the injured brain have been used to measure cerebral injury. Neuronal, glial, and endothelial cells of the CNS elaborate these substances in response to ischemia/reperfusion injury. Assays for these biochemical markers provide a relatively noninvasive means of quantifying the extent of neuronal injury. If these assays can demonstrate a direct correlation with clinical outcomes, these biomarker assays may offer a simpler way of assessing postoperative cognitive dysfunction. A recently investigated protein is ubiquitin C-terminal esterase-L1 (UCHL1), which is specific to neurons, is expressed in high concentrations in the CNS, and functions in the degradation of misfolded proteins. This serum biomarker correlates with neuronal injury in animal and human studies of subarachnoid hemorrhage and traumatic brain injury. In our laboratory, we detected serum elevations in this biomarker in animals subjected to neurologic injury after being exposed to a prolonged period of HCA. Current studies are underway to examine the usefulness of this biomarker in human patients undergoing CABG.

S100B is another candidate biomarker, which normally promotes axonal growth, glial proliferation, and neuronal differentiation. This protein is released by injured glial cells and also demonstrates increased blood concentration after cardiac surgery. It has been shown to correlate with intraoperative cerebral microemboli, quantified using TCD sonography. Furthermore, a significant correlation was detected with neuropsychological deficits assessed at 6 months postcardiac surgery in a small study of 16 patients. Many of the other previously studied CNS biomarkers, such as tissue-specific enolase, are limited by poor specificity or late detection. In addition to UCHL1 and S100B, recent experimental evidence suggests that spectrin breakdown products and glial fibrillary acidic protein have promise as useful biomarkers in the clinical setting of patients undergoing CABG. Although no CNS biomarker is used routinely at the present time, a reliable, noninvasive biochemical test for detecting early neurologic deficits would provide a great benefit to the postoperative care of CABG patients.
Magnetic Resonance Imaging

MRI has demonstrated cerebral edema as early as 1 hour after CABG. This is often clinically insignificant and resolves by 1 week. Diffusion-weighted MRI can also help to differentiate acute from chronic brain ischemia; however, it has been difficult to correlate the presence of lesions on MRI with clinical cognitive dysfunction. Magnetic resonance spectroscopy (MRS) is another useful adjunct, which may have better predictive value for cognitive dysfunction. We have used MRS in our laboratory canine HCA model, which has allowed us to detect and quantify subcellular metabolic changes within the brain after HCA. The most significant finding on MRS was a decline in the ratio of N-acetyl-aspartate to choline (NAA:Cho) 24 hours post-HCA, which is a known marker of neuronal mitochondrial dysfunction. MRS also provided a way of assessing the efficacy of different pharmacologic agents. Pretreatment with diazoxide limited neurologic injury versus controls, which was reflected in a preserved NAA:Cho ratio. These results could be correlated with the degree of clinical neurologic injury observed. Similarly, MRI/MRS and neurocognitive testing were performed serially during the pre- and postoperative period in a clinical study of 35 CABG patients. Transient changes were detected in the ratio of NAA to creatinine (NAA:Cr), with the degree of decline closely correlating with deterioration in neurocognitive function, increased patient age, and longer CPB times. Normalization of the NAA:Cr ratio also accompanied the recovery of neurocognitive performance over time. These studies clearly demonstrate that MRS may offer an early, noninvasive means of assessing neurologic injury and the effectiveness of neuroprotective agents.

CONCLUSION

Neurologic injury remains a significant complication after CABG. This is especially true given the continual improvements in surgical and anesthetic techniques that have enabled cardiac surgeons to operate on older and higher acuity patients today. Therefore, it is important that the individual risk profile of each patient be taken into consideration. The various neuroprotective strategies available to the cardiac surgeon continue to expand. Pharmacologic neuroprotection is an attractive option for preventing neurologic injury and therefore is a very active area of research. Although we have had success in some laboratory and small clinical studies, no single agent is available for routine use in CABG patients. However, as our fundamental understanding of the mechanisms of brain injury after cardiac surgery continues to improve, we will be better equipped to design enhanced neuroprotective strategies in the future.

SUGGESTED READINGS

EDITOR’S COMMENTS

These authors have presented the mechanisms of neurologic injury and potentially preventive strategies for prevention. There is no doubt in my mind that this is the most difficult area of comorbidity now facing cardiac surgery. Neurologic injury is a difficult area and clearly affects the present and future of our patients. I entirely agree with the authors about the avoidance of embolization as well as some of the preventive measures they have proposed. Dr. Baumgartner has studied the single cross-clamp technique for coronary bypass surgery and there is no doubt this is the way on-pump bypass surgery should be done. This is the technique we presently employ. The authors have also demonstrated that off-pump coronary surgery will not completely prevent neurologic injury.

I agree with the authors that there will be pharmacologic adjuncts that will help us in more complex cases including circulatory arrest. The Cardiothoracic Surgery Network sponsored by the NHLBI is reviewing several protocols that will potentially examine such agents. I believe we will have a totally different approach in the future to prevent these complications.

ILK
Patient Safety
Thoralf M. Sundt

The term "patient safety" is widely—and sometimes loosely—used today in a variety of contexts and it would convey a variety of meanings. The suggestion made over a decade ago that patients were unsafe in our hospitals was initially greeted with skepticism if not hostility but now has given way to acceptance as the medical community has come to recognize that there are indeed instances of avoidable harm. With a turn in focus to reducing "adverse events" and "errors," a veritable "movement" has arisen within the medical community.

The scope of the topic is enormously broad, encompassing equipment design to make their use more intuitive through legible and proximity-compatible information delivery and ergonomic structure, to process design to make them simpler and more resilient. Less obvious may be issues of teamwork and communication. While all aspects of medical error impact the entire medical community, for practitioners of diverse specialties the emphasis may vary. For pharmacists or medical oncologists, the area of greatest risk and hence greatest focus may be avoiding medication error. Surgeons have focused for many years on aspects of technical error. As the complexity of surgical care has increased, however, errors in nontechnical skills such as cognitive errors, communication errors, and errors in situational awareness have become more important. We will focus here on these domains in the interest of developing a basis for understanding the interventions proposed for the surgical arena. The potential impact of such interventions is powerful, as disruptions in teamwork and communication have been shown repeatedly to be strongly correlated with errors, outcomes, and even legal actions. Furthermore, the interventions required to improve teamwork and communication are almost entirely within our own personal control.

It is also worthwhile carefully defining our terms. "Error" as defined in the Institute of Medicine Report is "the failure of a planned action to be completed as intended or the use of the wrong plan to achieve an aim." As such, there is no blame implied nor is the occurrence of an adverse event requisite. Regardless of the clinical consequences, an error stands as an error just the same. Accordingly, its pathogenesis can be examined, as can any recovery efforts successful or not. Indeed many would argue that the most information one can gather is by examining "near misses" as they are more plentiful (thankfully) than adverse events, and that successful error capture and recovery has more to teach about resilient teams than uncorrected ones.

The meaning of the term "adverse event" is self-explanatory; an injury or complication occurring during medical treatment. Adverse events may be avoidable or not, and they may be related to an error or not. The focus on adverse events resulting from the patient's underlying condition has long been a staple of the medical literature, such as the incidence of dialysis-dependent renal failure and its association with comorbidities such as long-standing hypertension or diabetes. To be sure "patient safety" can be improved via interventions to mitigate that risk as well; however, more often when reference is made to patient safety efforts, it is in the context of adverse events occurring as a consequence of medical error, particularly those that might be preventable. Of course, not all adverse events lead to lasting or significant harm, and the definition of "preventability" is thorny as well. A narrow perspective may rest with the legal definition of negligence, which addresses whether or not care provided meets the standard of care that can be reasonably expected of an average physician in those same circumstances. On the contrary, a more liberal definition of preventability will likely lead to more progress in improving outcomes.

There has been significant argument over whether it is more productive to focus on errors or adverse events. Argument in favor of the former identifies them as the ultimate precursors and belies the presumption that prevention of error will reduce adverse events and preventable harm. The difficulty is that errors are so common that it can be overwhelming just keeping track of them. Those who argue in favor of a focus on adverse events suggest that such an approach with concentrate attention on the most serious errors worthy of attention. There really can be no resolution to this argument as both sides have merit. It is worth noting, however, that one must be clear about definitions at the outset. Improved safety will be the inevitable product of reducing all of these.

Although it was the Institute of Medicine report "To Err is Human" published in 2000 that raised the topic most prominently to our collective consciousness, the origins of this alternate perspective can be traced back at least as far as Ernest Amory Codman who challenged the medical community in Boston to adopt what de Leval has called a "forensic" approach to surgical outcomes in contrast to the more traditional "statistical" approach. Codman insisted on reporting of 1-year outcomes including the reasons why perfection had not been attained. He classified errors and adverse events and queried the role of human, organizational, and equipment factors. This approach was not welcomed in his home town or nationally. The same theme, however, was taken up by de Leval, initially surrounding the arterial switch operation in his own hands and subsequently in the United Kingdom broadly. The impact of even minor errors on outcomes was highlighted in this study, reported to the American Association for Thoracic Surgery in 1999, as was the role of "Human Factors" in general. He had begun his journey many years previously as told in this Lancet article "Human Factors in Cardiac Surgery: A Cartesian Dream," which represented a summary of his Mannheimer lecture focused on his own approach to technical errors after the death of a child early in his career due to a technical error. In it, he outlines the lessons to be learned from other disciplines and his journey into systems thinking, recognition of the impact of many factors beyond patient risk factors, and surgical skill on outcome. Importantly, such a perspective provided him and us a window into other opportunities to impact those factors and improve outcomes.
LEARNING FROM OTHERS

Among the fields de Leval encourages us to explore is that of human factors science. This field incorporates knowledge from cognitive psychology, engineering and industrial design, and ergonomics to understand human capabilities and limitations, and their impact on performance of tasks be they medical or otherwise. This understanding helps in the design of systems or technologies to reduce the chances of human error. While the origins of process design can be found in 19th century “time and motion studies” conducted to improve factory efficiency, human factors came into its own as a recognized field in World War II when aircraft became so remarkably complex that their operation exceeded the cognitive capacity of a single human mind. The result was an effort to design the plane to fit the human rather than vice versa. For example, Alphose Chapinis demonstrated that shape coding aircraft cockpit controls for the flaps and landing gear reduced landing accidents. It is because of the dramatic accomplishments in the field of aircraft engineering that the analogy between medicine and aviation is cited so frequently, sometimes to the chagrin of physicians. The analogy holds, however, as fundamentally the issue is human performance in complex environments. Closely related is the field of cognitive psychology including biases, heuristics, and intuitive decision-making.

The relevance of these fields to surgery resides in practical solutions to common human challenges in complex environments that have been explored and developed elsewhere but can be modified and applied in medical care in general and surgical care in particular. The cognitive aspects are particularly applicable to surgery and in particular cardiothoracic surgery, as our field demands a large number of decisions be made on the basis of incomplete information on a short time-line with profound implications for our patients. When things go wrong, we can apply the discipline of accident analysis to understand the potential interventions that might prevent the same in future. The applicability of the Human Factors Analysis Classification System, which was employed productively to reduce accidents among military pilots, to cardiac surgery has been demonstrated.

A nontrivial barrier to the application of forensic analysis and human factors science to healthcare is the fear of retribution either from peers or the legal system. The former is within our control even if the latter is not. In order to maximize our ability to learn from errors, it is necessary that we develop a “blame-free” culture in which errors can be openly discussed. This does not imply disappearance of accountability, but rather a reframing. Individuals are still accountable for their own actions such as willing rule violations or reckless behavior, whereas the accountability for systems issues is shared among those responsible for the systems themselves. In some instances, individual accountability is replaced by collective accountability—not disappearance of accountability. This concept has been termed “Just Culture.”

COMPLEXITY

It is reasonable to ask “why change from the way we have done things in the past?” Apart from concern about “political correctness” what is so different about medical care today? Why is a conscious focus on medical error is now necessary?

Just as occurred with rapid technological developments in the military during WWII, the complexity of our environment has increased exponentially in recent years. The body of surgical knowledge, the complexity of our technology, the composition of our patients, and the organizational complexity of medical institutions including interdisciplinary collaborations have made medicine a much different field today that only a few years ago. The consequences of this increased complexity are profound.

Complexity itself is now a field of scientific endeavor. Complexity theory and systems science focus on the properties of complex systems. Complex, interconnected systems behave as more than the sum of their parts. Complex systems are, by their very nature, nonlinear, sensitive to initial conditions, and self-organizing. The interactions among individual elements lead to unpredictability and unintended consequences. Perrow has argued convincingly on the basis of study of nuclear power, petrochemical plants, mines, deep-sea oil drilling operations, and marine commerce that accidents are inevitable—they are “Normal” in highly complex environments. The risks to the system as a whole posed by normal accidents depend in significant measure on the degree to which the interactions among system components are “tightly or loosely coupled” and our ability to capture them on whether the relationships are “linear or complex.” Ironically, technological “solutions” such as safety systems layered on top of these complex systems may simply make them even more complex and incomprehensible.

The implication if we wish to continue to make progress, then, is that we must develop means of dealing with such accidents. The so-called “High Reliability Organizations” (HROs) such as the nuclear power industry or flight-deck operations on aircraft carriers have done so. HROs are defined as organizations that must function reliably in highly complex environments in which the consequences of error are catastrophic. In such organizations, the focus is on error management—not just prevention—and anticipation of the unexpected; they focus on error identification, capture and recovery as well as the critical importance of resilience. Complexity is fundamentally best dealt with by decentralized control, and HROs demonstrate this in the manner in which they are structured.

HUMAN COGNITION

Recent years have seen marked advancements in our understanding of human cognition and an understanding of the strengths and limitations of the same. Metacognition—thinking about thinking—has become a topic of popular books and Nobel Prizes (Kahneman). An understanding of those cognitive processes and limitations are critical for surgeons called upon to make decisions quickly and under pressure on a regular basis. Uncertainty, time pressure, and the gravity of the decisions increase our vulnerability to error. For these reasons, it is important to understand how our brains work and, perhaps more importantly, when we are at greatest risk of making an error and means of mitigating this risk. Again, this is an area of opportunity for us to improve outcomes.

In order to deal with our complex environment and what would otherwise be an overwhelming number of sensory inputs, human perception demands application of filters; the consequence is systematic and predictable biases. Equally, to make decisions efficiently, we employ cognitive shortcuts or “heuristics.” Kahneman has identified two complementary cognitive systems—one fast and one slow—called system 1 and system 2 or more descriptively the automatic and contemplative or reflective. The former is more efficient in complex environments, particularly when time is of the essence. Unfortunately, it is also susceptible to pitfalls. Many of the interventions proposed to improve patient
Section II: Adult Cardiac Surgery

Some Common Pitfalls in Perception and Decision-Making

Hindsight bias: "I knew it all along" or "Monday morning quarterback"—refers to the tendency to view what has already happened as obvious. This is unfortunately the basis of many legal actions.

Confirmation bias: Refers to the tendency to dismiss disconfirmatory or contradictory evidence and cling to a theory or interpretation. When manifest among a collective, this phenomenon is referred to as "group think."

Representativeness bias: Refers to the tendency to overestimate the likelihood of an explanation or diagnosis based on its similarity to a memory of the same rather than the actual likelihood of the explanation (classically ignoring base rates). It derives from a reflex tendency to look for similarities.

Valence effect: The tendency to think positive outcomes to be more likely than negative ones. This is responsible in part for the Framing Effect (see below).

Certainty effect: The impact of a reduction in the probability of an outcome is greater if it can be eliminated completely.

Biases secondary to context

Contrast effect: Contrasted stimuli that are similar to each other tend to alter perceptions of each other. A circle surrounded by smaller circles "looks" larger than the same-sized circle surrounded by larger ones. Remarkably, it remains true even when one knows that the circles are of the same size!

Primacy effect: Perceptions tend to be overinfluenced by impressions made early, particularly when one is comparing opposite sides of an argument. This is why there is a subtle advantage to leading off in a debate. This effect is particularly apparent if the subject is queried soon after the impressions are made.

Recency effect: In contrast, in other instances, it is the final event that has the greatest impression. In this instance, one may best remember the last presentation in a debate more clearly. This is more apparent if the subject is queried late after the event. The same phenomenon accounts for the tendency to consider the same diagnosis today as one saw yesterday, even if less likely than another.

The Halo effect: The tendency to attribute additional characteristics to a person or phenomenon based on other characteristics (e.g., good looking and intelligent, etc.)

Framing effect: Responses will depend on the way in which the questions themselves are stated or framed, for example, closed versus open questions, the number of responses (many/few, odd/even), and losses versus gains such as mortality/survival.

Certainty effect: An opportunity to reduce the probability of an outcome is more impactful if the outcome was initially thought certain.

The endowment effect: Endowment effect or "loss aversion" refers to our tendency to overvalue that which we already possess (be it an object or an idea).

Regret theory: When making a decision we mentally simulate the possible outcomes and then compare the way we feel about the loss of either possible positive scenario.

Fig. 40.1: This example of the contrast effect, in which contrasted stimuli altered perceptions of the other, demonstrates the remarkable power of such illusions even when one is aware of the facts. Although the center circles are exactly the same size, the circle surrounded by larger ones looks smaller than its counterpart surrounded by smaller circles. The illusions persist even though one knows that the circles are in fact the same size.

Finally, again along the lines of understanding our own cognition, there is a growing body of knowledge about decision-making itself. Some of the biases mentioned...
in Table 40.1 directly impact decision-making. Beyond that, however, are theories of “expert decision-making” that again have direct relevance to surgery.

Expert or naturalistic decision-making stand in contrast to the means whereby novices make judgments and decisions. While novices think algorithmically, relying on “slow thinking” the way we were taught our craft, experts rely on intuition and “fast thinking” to increase speed and efficiency. This is how an expert comes to a diagnosis or course of action so quickly given a patient or situation similar to but not exactly like one they have encountered before. Rather than deductive, logical thinking including analysis of probabilities and use of statistical methods, in natural settings we look for analogous experiences as prototypes in a manner termed “recognition-primed decision-making” to size up a situation and mentally model possible solutions (and their pitfalls). These modes of thinking are particularly evident when experienced decision-makers are under time pressure to make high stakes decisions with inadequate information under dynamic conditions. This is surgery.

While efficient, this nonalgorithmic thinking has its weaknesses; it does not permit evaluation of alternate courses of action side-by-side because it does not list a series of options. It depends upon mental simulation of the course of action asking only “will it work.” The alternative strategy—the “rational choice” strategy employed by novices is time inefficient. Mental simulations can run awry, however, as we are prone to explain away contradictory information (confirmation bias) until the explanations themselves become so complicated that we lose faith and reexamine. Sensemaking can go wrong if we rely too much on our intuitions and expertise as our own mindset may make us blind to other explanations. This explains how we can be amazed by the medical student that twigs to the correct answer when all of the “experts” have been following the wrong path, or why we can be mystified at mortality and morbidity conference by our own blindness to what we “really going on.” It is also why listening to the input of “nonexperts” can be so valuable.

Added to these challenges is the biology of the sense of certainty. Unfortunately, perhaps, our confidence in decisions tends to increase as the difficulty of those decisions increases and, consequently, as the accuracy of those decisions approaches chance. Importantly, this discrepancy between accuracy and confidence is unrelated to intelligence. The involuntary “feeling of knowing” derives from the limbic system. Furthermore, the more uncertain the situation—due to missing information, incorrect information, conflicting information, noisy information, or confusing information—the more the decisions are based on emotion, instinct, and heuristics.

There are also important implications of this understanding for training: if we wish to train clinical intuition and expert decision-making, students need experience in actually making decisions and managing difficult cases. In years past, this was accomplished by long hours in the hospital. Today it may be possible to accomplish by developing training programs with intensive exercises and realistic scenarios demanding rapid action. Deliberate practice in decision-making with immediate feedback can actually improve this skill.

Note also that an understanding one’s own expertise is important when communicating to others. Many things that are obvious to experts are completely invisible to novices. One must take the time to explain how one has come to a conclusion or the patterns one sees that simplify the situation cognitively for you.

An additional cognitive challenge in identifying problems or pitfalls for surgeons in particular is termed “stance.” This term refers to your approach when carrying out the work. Are you focused on the performance of task itself or on identifying potential problems? It is difficult to do both, which is why the individual running a cardiac arrest code should not be the one actually performing cardiopulmonary resuscitation. And yet it is the nature of what we do that the operating surgeon must do both. Furthermore, it has been demonstrated that if continually interrupted one will be even more challenged in identifying problems. To some degree, this is an inescapable fact of life. It is also an argument again for engaging the rest of the team cognitively and leveraging all of the minds in the room.

The practical utility of this metacognition is in developing awareness of when and how one may misperceive a situation or make an erroneous decision and develop defenses. Checklists are one such defense, but only one, and they are useful for a particular type of cognitive error. They are useful for preventing memory lapses during the conduct of a sequence of steps that are the same every time and must be conducted in the correct order. They are particularly useful for the human–machine interface. They are decidedly not, however, a universal solution—they address only memory lapses. They do not address biases in perception or cognitive traps. The broadest solution is collective intelligence. This, in turn, demands effective communication and teamwork.

**HIGH RELIABILITY**

Other high risk/high consequence endeavors have adopted strategies to manage these same challenges via teamwork and collective intelligence. The so-called “High Reliability Organizations” can be defined as “Organizations that consistently avoid catastrophes in environments where normal accidents can be expected due to complexity.” They share a fundamental character: they are organized to expect, identify, and contain the unexpected. They exhibit resilience. Their aim is error management, not just error prevention. To accomplish this, they are organized around five principles:

- **Preoccupation with failure**: Lapses are taken seriously as a symptom that there is something wrong with the system.
- **Reluctance to simplify interactions**: Deliberate steps are taken to constantly update interpretations to create a complete and nuanced picture.
- **Sensitive to operations**: Recognition that unexpected events originate in latent failures that are revealed during normal operations on the front line.
- **Commitment to resilience**: Deliberate development of capabilities to detect, contain, and recover from inevitable errors.
- **Deference to expertise**: Decisions need to be made where the expertise is—on the front line.

Managing the unexpected demands an understanding of the expected and how expectations are shaped and, in turn, how to manage those expectations mindfully. As noted above, cognitive filters based on expectations are necessary to deal with any complex environment. Importantly, mindfulness demands more than situational awareness—it demands ongoing questioning of expectations and a willingness to accept new interpretations. The focus is on emerging threats and potential means of dealing with them. We see this in the experienced surgeon who asks, “What is the danger at this point in the operation and what options do you have to deal with it if it occurs?” The key cultural components are a reporting culture, a just culture, a flexible culture, and a learning culture.
Dealing with the unexpected demands resilience—an ability to remain in control despite external or internal challenges. Resilience demands an ability to (1) absorb strain, (2) to bounce back rather than collapse, and (3) to learn from the experience. These can be properties of both individuals and organizations alike. Importantly, accomplishing these aims demands flexibility. Unfortunately, at an institutional level, all too often the response is to implement rules and regulations that reduce flexibility. Worse, they may actually increase the complexity of getting the work done and absorb more of the cognitive capacity needed for adaptive thinking. The most powerful tool is teamwork.

TEAMWORK

The most powerful countermeasure to pitfalls in perception and decision-making is effective teamwork. Collective cognition—harnessing the diversity of expectations, biases, and perspectives—enables effective error management and resilience. High-level teamwork, in turn demands effective communication, cooperation, and coordination. This is the contribution of complex sociotechnical systems theory as applied to the problem of medical error. The interactions and interfaces are the key to high reliability and improved outcomes as suggested by de Leval in his Mannheimer lecture.

Miscommunication—be it due to ineffective “encoding” of the message because of vague, ambiguous, or incomplete language; inaccurate decoding; or misdirection to the wrong individual—obviously undermines teamwork. It stands in the way of establishing “shared mental models” or “common ground” for sense making. The problems of language have, perhaps unsurprisingly, been particularly studied in aviation where recordings of communications among pilots and between pilots and air traffic controllers provide a unique window. The parallels to the operating room are clear; problems of ambiguity (such as when a surgeon says “OK” meaning “go on bypass”), homophony (an increasing problem among staff for whom English is a second language—“on” and “off” can sound a lot alike), punctuation and intonation as well as problems of reference (does “vent on” refer to the LV vent or the root vent?), and problems of inference (either false or absent as in the case when an assistant suggests “are you sure that you did not leave a sponge behind?” meaning “you left a sponge behind the heart”) are encountered daily. This is the basis of emphasis on structured communication in aviation and the military. Even if language is clear, and situational awareness is common, the presence of hierarchy may present a barrier to “speaking up.”

 Formal programs in team training and communications abound; while they have proven effective in aviation, and initially so in health care, their impact in the latter has proven difficult to sustain. TeamSTEPS is a program developed by the Department of Defense in cooperation with the Agency for Healthcare Research and Quality and is freely available but appears to demand continued coaching. Surgeons and human factor scientists in the United Kingdom developed the Nontechnical Skills for Surgeons program, but its roll-out to U.S. sites has been limited.

An alternative approach, favored by the author, has been the institution of structured, participatory briefings. Their implementation is low-technology and time-efficient, and the impact appears durable as long as the prescribed behaviors are sustained. Participatory preoperative briefings establish multidirectional dialog, such that if and when problems arise, team members are more likely to speak up. They have been shown to reduce flow disruptions and waste even when instituted among familiar teams. The participatory aspect is enhanced if the order of speaking is in reverse order of hierarchy or empowerment. The effectiveness of this approach during briefings or, indeed, during floor rounds, is remarkable. In addition, a conscious effort can be made to invite and celebrate the mindful engagement of the entire team in the care of the patient. Suggestions should be welcomed even if not taken.

ACCOUNTABILITY

Finally, a word about accountability; the movement toward a “system perspective” and focus on teamwork itself presents unique challenges, with regard to accountability. The “system perspective,” recognizes that the operation of a system is critically influenced by the nature of the interactions among the components of the system. Therefore, understanding of the function and the faults demands a holistic approach. In this context, accountability for those functions and for those faults may well lie within the system itself. Furthermore, identification of those system issues is most effective in a “blame-free culture” in which errors are readily identified or confessed without fear of retribution. The individual should not be blamed for systemic problems. Who then is accountable? Is the individual ever accountable? Is no one accountable?

The balance must be struck between appropriate accountability and absence of accountability. In an era before systems factors were acknowledged, it was clear who was “accountable” even if they were not to blame! With a systems focus there is the risk that “nobody is to blame” but the system. The alternative is collective accountability of the team.

A related concept is that of “Just Culture” in which we can satisfy the demands for accountability while also allowing for reporting and learning. It distinguishes between unintended errors and negligence, recklessness, and knowing rule violations. In another construct from James Reason’s work, errors may be skill based (such as accidental slips or lapses) or mistakes (either rule-based or knowledge-based). More simply still, Charles Bosk distinguishes between technical and normative errors, the latter being regarded much more negatively in surgical culture. In practice, one may ask the question whether another well-intended, unimpaired individual under the same circumstances may have committed the same action—if so the individual should not be blamed.

SUMMARY

Patient safety can most productively be considered as the product of a reduction in preventable adverse events leading to patient harm. Not all adverse events are the consequence of errors, but many if not all preventable events are likely so. Accordingly, a focus on errors of all types can be expected to improve patient safety. Errors may be due to organizational/systems issues, device design issues, process design, or individual human performance including both technical and nontechnical matters. As leaders within our institutions, we should each contribute productively to improvements in systems of care. As innovators, we may be able to contribute to device design in collaboration with our industry partners.

Most immediately, however, each and every one of us can improve the performance of our teams. We are all humans and as such are subject to recognized human fallibilities. Our brains have evolved to accomplish remarkable tasks, and at the same time demonstrate remarkably consistent vulnerabilities. These limitations have been recognized in other industries and countermeasures developed,
which may be considered for modification and application to health care in general and surgery in particular. Optimal safety demands high team performance, which in turn depends upon effective leadership skills. These nontechnical skills can be learned. Social intelligence and emotional intelligence should be recognized as important skills and developed. Optimizing the performance of your team requires active effort and is a critical part of our jobs as leaders and care providers. We will provide the best outcomes to our patients through effective teamwork. This is the most direct path to transforming surgical practice into a high reliability endeavor.

**EDITOR'S COMMENTS**

This chapter on Patient Safety by Dr. Sundt is a new addition to this book. We as surgeons have tended to base our results on the last best or worst case. Clearly, this is an inaccurate and inappropriate technique for improving performance. We have done better studying databases and looking at collective results.

Dr. Sundt has demonstrated much more expert approaches to patient safety and avoidance of error. In particular, he emphasizes a blame-free environment and a team approach to the patient. This is easier said than done. He discusses the approach of briefing and a discussion process that includes all members of the team. In addition, he presents the example of the person who attends a cardiac arrest and runs a code.

One must be able to step away from the emotion and physical resuscitative actions to best reduce error and improve outcome. To say the least, this is a new area for all of us. We are being judged on patient safety by groups such as Leap Frog and Consumer Report. There is no doubt this will continue to be emphasized and improve as we learn the skill sets to truly deal with this.

ILK
Reoperative Cardiac Surgery—General Principles
Damien J. LaPar and Irving L. Kron

CARDIAC REOPERATION
Reoperations for cardiac surgery following prior sternotomy are associated with elevated morbidity and mortality. Major adverse events occurring in the intraoperative and perioperative setting are often predictable but may still occur despite careful attention and surgical detail. As cardiac reoperations are fundamentally different from routine, nonoperative cases, the general approach to patient selection, preoperative assessment, and surgical technique should be modified from that commonly employed in the routine, nonoperative setting. In fact, certain advantages may be derived from a protocol-driven approach to reoperations to improve surgical technique and patient outcomes. This chapter reviews general principles that apply to the preoperative and intraoperative management of patients undergoing cardiac reoperations following prior sternotomy.

INCIDENCE AND POSTOPERATIVE OUTCOMES OF REOPERATION
Performance of cardiac operations after prior sternotomy continues to confer an increased risk of operative mortality and morbidity. Recent trends indicate that the performance of cardiac reoperations has been affected by an increase in patient life expectancy and by improved patient outcomes following primary cardiac operations. While evidence demonstrates that the number of patients requiring reoperations for valvular disease has increased, those requiring reoperations for coronary disease has decreased due to improved secondary medical management and evolving surgical techniques. Mortality rates, nonetheless, remain elevated for a variety of cardiac reoperations, including those with prior coronary artery bypass grafting (CABG) and cardiac valve procedures. In a retrospective review of 946 cardiac reoperations performed at our institution from 1995 to 2010, the overall operative mortality was 8.2%. According to recent estimates from the Society of Thoracic Surgeons and other single institutions, mortality for reoperative aortic valve replacements (AVRs) range from 5% to 14%; however, we have recently demonstrated that improved outcomes for reoperative AVRs can be achieved and may, in fact, be comparable to that of primary operations (2.0% vs. 3.5%; \( P = 0.65 \)). We believe that the improved outcomes for cardiac reoperations observed over time are due to enhanced approaches to patient assessment and selection as well as intraoperative management.

PREOPERATIVE PLANNING
Patient selection and assessment for cardiac surgery following previous sternotomy begins with a comprehensive history and physical exam. A thorough medical history should be conducted to include not only an extensive cardiovascular history but also a detailed history related to prior cardiac surgical interventions or surgical procedures within the thorax and mediastinum. Specifically, special attention should focus upon the type, date, and nature of prior cardiac operations, prior incisions and thoracic approach, and postoperative complications following prior cardiac operations, including respiratory failure, tracheostomy, and sternal wound infections. In addition, a prior history of mediastinal infections, previous chest irradiation, number of cardiotomies, prior pericardectomy, number, conduit type, and location of previously performed CABGs, and prior implanted valve size and type should be considered. Previous operative notes must be carefully reviewed.

A complete physical exam should be performed. Particular attention should be paid to important findings related to a prior cardiac procedure. In addition to routine physical exam techniques, prior surgical scars on the chest should be assessed for location and extent of healing. Whether a prior cardiac procedure was performed through standard full or partial median sternotomy, thoracotomy, or other minimally invasive approaches often provides valuable insight into the degree of underlying scar tissue that may be encountered upon resternotomy and which may alter existing mediastinal anatomy. Degree of prior wound healing and overall appearance of prior scars may provide additional insight into the setting of prior wound infection, breakdown, or deep sternal wound infection. Potential graft conduit sites should also be considered during the performance of the physical exam for reoperative cases requiring myocardial revascularization. This assessment includes evaluation of both upper and lower extremity venous and arterial conduit sites, including the performance of bilateral Allen tests to assess for collateral flow in patients who may be candidates for radial artery CABGs. Similarly, peripheral vascular access sites for potential femoral or axillary cardiopulmonary bypass cannulation should be assessed for patency, prior scars, and ease of access.

Cardiac Catheterization
Standard preoperative evaluation with routine catheterization is fundamental to success for cardiac reoperations. In addition to routine preoperative laboratory analysis, chest roentgenography, cardiac electrocardiography, and echocardiography, all patients undergoing cardiac reoperations in the setting of prior CABG should undergo coronary angiography within 3 to 6 months of surgery to assess for graft orientation, to determine graft patency, and to establish the contribution of each graft to myocardial perfusion. Coronary angiography also helps to determine the location and proximity of previously placed
bypass grafts in cases of graft adherence to the sternum. This information is crucial to avoid injury and to develop a preoperative plan for myocardial revascularization in the event of intraoperative injury. Timing of preoperative angiography is an issue that affects patient morbidity and mortality. Recent series have demonstrated that contrast loads provided within 24 hours of operation result in significantly higher rates of postoperative renal failure, translating into higher mortality rates and increased hospital lengths of stay and resource utilization. At our institution, we favor cardiac catheterization ≥48 hours prior to operation in order to limit renal dysfunction in the postoperative setting.

**Radiographic Evaluation**

Preoperative computed tomography (CT) should be performed as part of the evaluation of all patients undergoing cardiac reoperations. More specifically, computed tomography angiography (CTA) provides a more complete radiographic assessment of mediastinal anatomy, architecture, and location and status of prior CABG. CTA has many advantages over other imaging modalities due to its ability to provide cross-sectional imaging, which can often be used to provide three-dimensional reconstructions of the heart and mediastinum (Fig. 41.1). Preoperative information that can be obtained from CTA includes the proximity of sternal incision to various mediastinal structures such as the right ventricle, aorta, pulmonary artery, CABG, and other vascular structures crossing the mediastinum. Details related to aortic size and degree of aortic calcification also aid in cannulation and cross-clamping strategies.

![Fig. 41.1](image)

**Fig. 41.1.** Representative preoperative computed tomography angiography cross-sectional (A and B) imaging with three-dimensional reconstructions (C–F), demonstrating a patent left internal mammary artery coronary artery bypass graft (arrows) that is in close proximity (4 mm) to the retrosternum and is at high-risk for reentry injury upon resternotomy.
prior to incision. The use of prior synthetic materials or felt pledgets may also be suggested by the presence of dense adhesions visible on preoperative imaging that may ultimately distort retrosternal anatomy and place cardiac and vascular structures at increased risk for reentry or intraoperative injury. Alternatively, for patients with baseline renal insufficiency of allergies to intravenous contrast, noncontrast CT imaging or magnetic resonance imaging can be performed.

The utilization and benefits derived from preoperative CTA or CT for cardiac reoperations appears to be increasing. Cremer and colleagues demonstrated a 98% safe reentry rate and low injury rate (2%) in their study of patients undergoing reoperative CABG following assessment with preoperative CTA. Other series have reported on the role of preoperative CT imaging to develop alternate surgical strategies in up to 80% of cardiac reoperations. In one of the largest reported series to date, the benefits of establishing cardiopulmonary bypass via peripheral cannulation prior to sternotomy was demonstrated in the setting of dense retrosternal adhesions identified by preoperative CT. Most importantly, the use of preoperative CT imaging has been shown to reduce postoperative morbidity including reentry injury and postoperative stroke rates, and at our institution it remains routine practice to obtain and review preoperative CT imaging on all patients undergoing reoperations following prior sternotomy.

Other Considerations

Several other important considerations exist for patients undergoing reoperative cardiac surgery. Adequate peripheral intravenous and arterial access is required prior to induction of anesthesia. This often requires placement of two central venous catheters and two peripheral arterial lines for adequate monitoring and resuscitation in the event of a life-threatening reoperation. Choice of arterial line placement is important. If the radial artery is a potential CABG conduit, the contralateral radial artery should not be accessed for arterial line placement. Patients undergoing reoperations also have a higher prevalence of prior pacemaker and automatic implantable cardioverter-defibrillator devices (AICDs). Consequently, the placement of external defibrillator pads prior to induction is recommended, and the function and type of all implanted devices should be reviewed and interrogated prior to surgery. Finally, the treatment mode of all AICDs must be turned off prior to induction.

INTRAOPERATIVE CONSIDERATIONS

Intraoperative Patient Preparation

Intraoperative preparation of the reoperative cardiac surgery patient begins immediately upon the patient’s arrival to the operating room. A quick review of preoperative imaging, studies, and cannulation strategy is paramount to operative success. We recommend that all the available preoperative cardiac catheterization and cross-sectional radiographic imaging are displayed in the operating room upon patient arrival. Next a reevaluation of all prior scars including primary incisions, prior drain sites, and graft conduit sites should be performed. Potential access sites for extrathoracic, alternative cardiopulmonary bypass cannulation (femoral and axillary) should be marked. At our institution, placement of femoral arterial and venous guidewires is performed for all cardiac reoperations in the event that alternative cannulation is required for cardiopulmonary bypass support. This is most commonly performed percutaneously using the Seldinger technique and soft-tipped wires. The wires are then secured appropriately to prevent migration or accidental removal. The patient should then be prepped and draped in the usual sterile fashion to the extent that all alternative, extrathoracic cannulation and potential graft conduit sites are included in the surgical field. At this point, all cardiopulmonary bypass lines should be brought to the surgical field, and the bypass pump should be primed and ready prior to sternotomy in the event that it becomes necessary to emergently initiate cardiopulmonary bypass.

Incision and Dissection

The choice of incision for reoperation is most appropriately left to the discretion and experience of the operating surgeon. For the majority of cardiac reoperations, standard median resternotomy is most appropriate. Alternatively, a thoracotomy may be used; however, this has been associated with higher risk of postoperative stroke and may limit the ability for myocardial revascularization. For resternotomy, the sternal skin incision and dissection of the sternum are carried out in the standard surgical manner. Prior sternal wires are then removed. We do not routinely recommend leaving wires in place to protect the mediastinum during division of the anterior and posterior tables of the sternum as this not only limits the ability to control an injury upon sternal reentry but also can result in multiple wire fragments that can prove injurious to underlying mediastinal structures.

Careful mediastinal dissection is fundamental to success during cardiac reoperations. The primary goal of mediastinal dissection is to liberate available cardiopulmonary bypass cannulation and appropriate aortic cross-clamp sites. While preoperative radiography often provides enough detail to develop an adequate cross-clamping strategy, occasionally intraoperative surveying of aortic architecture is required to minimize the disruption and embolization of aortic plaque and calcifications. Minimal manipulation and dissection of the aorta also reduces the likelihood of subadventitial dissection. Overall, the “golden rule” of reoperative cardiac dissection is that only areas necessary for the planned procedure should be dissected. During reoperation, it is customary at our institution to perform minimal mediastinal dissection, to practice a no-touch operative technique for prior CABGs, and to not routinely clamp the internal thoracic artery for cases following a prior CABG. Furthermore, for patients undergoing reoperations for isolated valve repair or replacements, it is not necessary to dissect out the left side of the heart, and it is acceptable to leave adherent pericardium to the right atrium to avoid injury if extensive adhesions are encountered. Other considerations include the use of sharp dissection around prior conduits and vessels to avoid thermal injury from electrocautery. Electrocautery can predispose to ventricular arrhythmias during mediastinal dissection. For difficult, high-risk reoperations, initiation of early cardiopulmonary bypass can also aid mediastinal dissection by decompressing the heart.

Cardiopulmonary Bypass and Cannulation

Cardiopulmonary bypass can be initiated either prior to or following resternotomy or thoracotomy, and the choice for either peripheral or central cardiopulmonary bypass cannulation is often dictated by the surgical risk of the case and the quality of vasculature available. While central bypass cannulation is often preferred, extensive calcification of the ascending aorta, a high number of prior central cannulations,
multiple patent bypass graft anastomoses to the aorta, presence of significant adhe-
sions to the right atrium, or patients at high risk for catastrophic injury to medi-
astinal structures may require alternative cannulation strategies. In these situations,
either axillary or femoral cannulation may be performed. For axillary cannulation, the
axillary artery can be easily accessed via vascular cut down performed in the deltoid
crease. Alternatively, the femoral artery may be accessed percutaneously using a
Seldinger technique or through a femoral cut down technique in the inguinal crease.
The choice of axillary versus femoral cannu-
lation is often dictated by the preoperative
assessment of individual patient vascular-
ture. Axillary artery cannulation has been
associated with reduced risk of limb isch-
emia and cerebrovascular complications
compared with femoral access, and the
femoral artery usually carries a higher ath-
erosclerotic burden. Complications of axil-
ary cannulations include brachial plexus
injuries, and the most serious immediate
complication of femoral access includes the
risk of vascular perforation and retroperi-
toneal hemorrhage. Regardless of choice in
peripheral arterial cannulation site, howev-
er, it is important to serially assess peripheral pulses following decannulation
in order to address early limb ischemia and
the potential for evolving vascular dissec-
tions and pseudoaneurysms.

The initiation of cardiopulmonary bypass should be dictated by opera-
tive risk. For most cardiac reoperations,
cardiopulmonary bypass should commence
following complete of all medias-
tinal dissection in order to reduce the
overall pump times and avoid any added
morbidty associated with prolonged
cardiopulmonary bypass. However, in
certain high-risk cases, the early initiation
of cardiopulmonary bypass has impor-
tant advantages and implications. For
cases with anticipated difficult medias-
tinal dissections or those carrying a high
risk of reentry cardiac or aortic injury, the
initiation of bypass prior to resternotomy or
thoracotomy is advised. In these scenar-
ios, bypass not only decompresses the heart
in order to reduce the overall pump times
and avoid any added morbidity associated with prolonged
cardiopulmonary bypass. However, in
certain high-risk cases, the early initiation
of cardiopulmonary bypass has impor-
tant advantages and implications. For
cases with anticipated difficult medias-
tinal dissections or those carrying a high
risk of reentry cardiac or aortic injury, the
initiation of bypass prior to resternotomy or
thoracotomy is advised. In these scenar-
ios, bypass not only decompresses the heart
in order to reduce the overall pump times
and avoid any added morbidity associated with prolonged
cardiopulmonary bypass. However, in
certain high-risk cases, the early initiation
of cardiopulmonary bypass has impor-
tant advantages and implications. For
cases with anticipated difficult medias-
tinal dissections or those carrying a high
risk of reentry cardiac or aortic injury, the
initiation of bypass prior to resternotomy or
thoracotomy is advised. In these scenar-
ios, bypass not only decompresses the heart
in order to reduce the overall pump times
and avoid any added morbidity associated with postponed
by the avoidance of additive surgical repair
of reentry injuries or myocardial revascular-
ization. It is our practice to initiate cardiopulmonary bypass prior to sternotomy for
cases with a high potential for aortic injury.

**A PROTOCOL-DRIVEN APPROACH TO CARDIAC REOPERATIONS**

A routine protocol-driven approach to preoperative assessment and intraopera-
tive management of patients undergoing cardiac reoperations can prove useful
in reducing patient morbidity and mor-
tality. At our institution, we have incor-
porated a protocolized approach to preoperative planning and operative
strategies employed for all cardiac reopera-
tions. Our protocol utilizes routine preoperative CTA or noncontrast CT to evaluate mediastinal anatomy and location
and status of bypass grafts, the placement
of soft-tipped arterial and venous femor al
guidewires in all reoperative patients prior
to induction of anesthesia, minimal medi-
astinal and cardiac dissection, no dissection
of prior internal mammary artery or other
bypass grafts, and early initiation of car-
diopulmonary bypass prior to sternotomy for
cases with a high potential for rester-
notomy or aortic injury. As a result, among
946 patients undergoing reoperations from
1995 through 2010 at our institution, the
adoption of this routine, protocol-driven
approach has resulted in a significantly
decreased incidence of re-entry injuries
(2.6% vs. 9.6%; P < 0.001) and lower operative
mortality (5.8% vs. 9.6%; P = 0.04) compared with reoperations performed
without the routine performance of these
measures. In an era of increasingly complex
cardiac reoperations, we suggest the adopt-
on of a similar protocolized approach to the preoperative and intraoperative
management of patients undergoing reopera-
tive cardiac surgery.

**CONCLUSION**

Cardiac reoperations following prior sternot-
omy are becoming increasingly performed
within the United States and worldwide as
patient life expectancy increases and patient
outcomes following cardiac surgery con-
tinue to improve. General principles guiding
the approach to cardiac reoperations should
incorporate many unique measures for ade-
quate preoperative patient assessment and
intraoperative management. Adoption of a
routine protocol-driven approach to cardiac
reoperations should be considered to reduce
intraoperative injury and postoperative
outcomes.

Drs. LaPar and Kron have given a comprehensive review of the general principles to be considered in reoperative adult cardiac surgery. Emphasis is placed, as it should be, on proper preoperative evaluation and planning to include a CT angiogram of the chest and coronary angiogram to determine the location and status of important structures such as bypass conduits. The strategies employed at their institution are those in common practice.

The authors emphasize the increased mortality rate for reoperative surgery, which should be discussed with the patient and family. The operative strategy they employ is to place arterial and femoral lines in case of the need for emergent peripheral bypass in the event of cardiac injury on reentry. In cases at high risk for such injury (such as a patent internal mammary artery graft in a precarious position), consideration should be given to surgical exposure of the femoral artery and vein prior to sternotomy to decrease the time required to initiate cardiopulmonary bypass. In low-risk cases, surgical exposure of the femoral vessels may be avoided. Compatible blood for transfusion should be available and in the operating room at the time of sternal reentry in the event of serious bleeding. The cardiopulmonary bypass machine should be primed and lines in place on the sterile field.

The authors describe the removal of the sternal wires in order to eliminate the risk of fragments injuring surrounding structures and reduce the time needed for a more emergent reentry. Our group and many others follow this practice but many groups also leave the wires in place as a safety measure to prevent entry of the saw into the right ventricle. There are groups that use a standard reciprocating sternal saw for redo-sternotomy, although the vast majority use an oscillating bone saw. Having the “feel” of the location of the posterior plate is easier with the hands in a relaxed neutral position and the use of lower saw speed. Additionally, heavy scissors may be used to divide the posterior table under direct vision.

Once the sternum is reopened, the emphasis should be on formulating a clear strategy, usually starting with the goals of aortic and right atrial cannulation for initiation of cardiopulmonary bypass. The obtuse margin of the right heart is often free of adhesions once the initial top layer is entered. One should not randomly dissect the heart but instead have a clear series of stepwise goals in mind: right atrium clear enough to cannulate, aorta able to be cannulated, aortic cross-clamp able to be placed, cardioplegia and vent lines able to be placed, caval tapes when needed, and so on.

Reoperative cardiac surgery requires a “bag of tricks” to fit various patients. Whether it be alternative cannulation sites (i.e., axillary cannulation), alternative cardioplegia cannulation (percutaneous retrograde cardioplegia coronary sinus catheter placement by anesthesia), or even circulatory arrest prior to sternotomy as in the case of large arterial pseudoaneurysms, these procedures should be performed by surgeons with significant experience in reoperative procedures.

There is no substitute for careful and thoughtful preoperative strategic planning for these operations. 

TSG and LRK
Mitral valve repair is one of the most important technical advances in cardiac surgery over the past 35 years and is the treatment of choice for most conditions of the mitral valve, most notably the prolapsed valve with myxomatous degeneration. This chapter outlines the current concepts and reparative techniques for the myxomatous degenerated mitral valve. Elements of the pathoanatomy and principles of repair will be reviewed followed by a detailed explanation of the surgical techniques used and refined at the Brigham and Women’s Hospital by the lead author over a 40-year career. Select adjunct techniques popularized at other major centers throughout the world are also discussed.

DEVELOPMENT OF TECHNIQUES OF MITRAL VALVE REPAIR

Elliott Carr Cutler at the Peter Bent Brigham Hospital did the first successful operative repair of the mitral valve in 1923. The surgery was performed on a 12-year-old girl diagnosed with severe rheumatic mitral stenosis. Using a neurosurgical tenotomy knife via a median sternotomy, Cutler, boldly and ingeniously inserted the knife transapically into the left ventricle of the beating heart, incising each fibrotic commissure in a blinded manner. Isolated successes with this operation were rare. It was not until after World War II, when Harken in Boston and Bailey in Philadelphia popularized the method of closed mitral commissurotomy for mitral stenosis using the finger fracture technique, that reasonable surgical successes were achieved for the management of what was inevitably a terminal disease. For the next 25 years, until the early 1970s, the closed mitral commissurotomy procedure was one of the most widely utilized techniques to treat and relieve mitral stenosis.

Similar to severe mitral stenosis, severe mitral regurgitation was also recognized early on to incur adverse outcomes prompting similar though more sporadic attempts at surgical correction. Yet unlike the surgical successes garnered with mitral stenosis, mitral regurgitation generated little in the way of innovative progress or reproducible surgical techniques until the development of the heart–lung machine in the mid-1950s. In the late 1950s and early 1960s, several suture annuloplasty techniques were developed to relieve mitral regurgitation with a modicum of success. One of the more successful attempts to relieve mitral regurgitation at the time was a technique developed by Harold Kay in Los Angeles who obliterated the commissures using a sequence of mattress sutures. A circular technique developed by Paneth and DeVega, involving a circumferential suture around the annulus, also aided in the early attempts at mitral valve repair. In the early 1960s, Dwight McGoon proposed a reparative technique for the degenerative prolapsed mitral valve with ruptured chordae that involved resecting a small segment of the mitral leaflet from the mitral valve. He rationalized that small resections of the mitral leaflet would prevent overall distortion of the valve and in the few cases where it was trialed the technique proved successful. However, with the advent of prosthetic devices to replace the mitral valve in the early 1960s, efforts to repair the mitral valve quickly waned with mitral valve replacement emerging as the preferred treatment choice for mitral regurgitation at the majority of institutions.

One of the ironies of the early 1960s was that most surgeons of the era believed it prudent to cut the papillary muscle and all chordal attachments to the mitral leaflets to ensure an anatomically secure mitral valve replacement. It is now recognized that utilizing chordal sparing techniques to preserve the subvalvular apparatus and annular-papillary continuity during mitral valve replacement retains left ventricular geometry. This portends to improve left ventricular mechanics and left ventricular function. Late cases of severe left ventricular decompensation and cardiomyopathy began to emerge in patients having undergone corrective surgery for mitral regurgitation where the chordal attachments were excised. Poor outcomes in these early experiences with corrective surgery for mitral regurgitation caused many surgeons to retreat from such operations. And cardiologists for their part became reluctant to refer such patients to surgery as a treatment option. A lack of appreciation for the importance of the subvalvular integrity when performing mitral surgery, which resulted in suboptimal outcomes, in addition to the prevailing yet erroneous “pop off” theory of the time, sustained the reluctance to intervene on the regurgitant mitral valve for many years. The “pop off” theory was the misconception that if a patient had progressed to having left ventricular dysfunction secondary to mitral regurgitation, the regurgitant valve was now a necessary evil, as it became a “pop off” valve into the left atrium that relieved stress on the failing heart. Any effort to correct the mitral valve in this situation was presumed to impart further stress on the already failing ventricle and thus cause deleterious effects. These two key misconceptions, removal of the subvalvular apparatus and the fallacious “pop off” construct, stymied advancements in surgery to treat mitral regurgitation well into the 1980s.
The late 1970s and early 1980s heralded a new development in mitral valve reconstructive surgery with the invention of prosthetic remodeling annuloplasty rings. The works of Alain Carpentier and Carlos Duran, pioneering surgeons independently credited with first implanting prosthetic rings during mitral valve reconstructive operations to refashion and remodel the mitral annulus, were seminal developments. The concept of implanting a prosthetic remodeling annuloplasty ring enabled mitral valve reparative procedures to be performed in a reproducible manner by surgeons worldwide. Along with the introduction of prosthetic rings to aid in annular remodeling, these two surgeons are credited with outlining the basic principles of mitral valve repair for the generations of cardiac surgeons to follow. In 1983, as an honored lecturer of the American Association for Thoracic Surgeons, Dr. Carpentier gave the now classic lecture entitled, “The French Correction,” outlining the basic principles of repair for the prolapsed mitral valve and emphasized the importance of an annuloplasty ring. This lecture helped to stimulate the thought process of the cardiac surgery community regarding the surgical treatment of patients with mitral regurgitation. A number of surgeons have subsequently developed rings of different caliber, consistency, and shape. Though the multitude of rings now available each profess their advantages over one another, the basic fundamental principles to mitral valve repair remain faithful to the initial tenets outlined by Carpentier and Duran, with a key tenet being the integral importance of an annuloplasty ring to remodel the annulus for long-term success. A commitment to annuloplasty ring implantation, more so than the type of ring implanted, is a far more important factor for successful outcomes.

**PRINCIPLES OF MITRAL VALVE REPAIR**

The principles of repair for the mitral valve have evolved with experience for each of the four etiologies of mitral regurgitation: rheumatic, endocarditic, ischemic, and myxomatous. Regardless of the etiology, the principles are basically the same: (1) create apposition of the anterior and posterior leaflets during systole, (2) increase valve mobility, (3) prevent valve stenosis, (4) reduce annular dilatation, (5) remodel the annulus, (6) prevent systolic anterior motion (SAM) of the mitral valve into the left ventricular outflow tract causing obstruction. Whereas the focus of this chapter is primarily the myxomatous mitral valve, other chapters of this textbook very explicitly outline reparative techniques for rheumatic, ischemic, and endocarditic mitral valve disease.

**REPARATIVE TECHNIQUES FOR THE MYXOMATOUS DEGENERATED MITRAL VALVE**

The following principles of mitral valve repair for degenerative mitral valve disease are now commonly accepted: (1) apposition of the posterior and anterior leaflets during systole, (2) reduced height of the posterior leaflet such that the prolapsing segment of the posterior leaflet is obliterated or reduced causing the overall height of the leaflet to be shortened, (3) stabilization of the anterior leaflet by repairing and replacing ruptured chords or shortening very elongated chords, (4) remodeling the annulus, which is distorted and distended using an annuloplasty ring. The annuloplasty ring may be a full encircling ring or a partial C-band, either rigid or flexible.

Conventional terminology used to describe the normal segments of the posterior and anterior mitral valve leaflets are depicted in Figure 42.1A. The surgical anatomy of the mitral valve and adjacent structures are illustrated in Figure 42.1B.

Apposition of the anterior and posterior leaflets in systole is fundamental to providing a durable mitral valve repair. The optimum level at which the leaflet apposition creates a tight coaptation point preventing any leakage across the valve can be determined by the “Carpentier” reference point in unaffected areas of the posterior leaflet in comparison to the anterior leaflet. Once this reference point has been identified, adjacent segments of the mitral leaflets where the reference point has not been adhered to, denotes those areas of the valve

![Fig. 42.1. (A) Anterior and posterior segments of the mitral valve. The normal partitions of the anterior and posterior leaflets of the mitral valve are illustrated. The leaflets appear in their closed position obscuring the valve orifice. Conventional terminology, used to describe and measure optimal points of repair, designates the anterior leaflet “A” and the posterior leaflet “P.” The leaflets are then divided into three segments designated as 1, 2, and 3 moving left to right from the anterolateral commissure toward the posteromedial commissure. (B) Surgical anatomy of the mitral valve. Thorough familiarity with the surgical anatomy of the mitral valve is key to avoiding injury to the coronary vasculature and other surrounding structures during reparative procedures.](image-url)
where alterations to the height of the leaflets need to occur so as to restore a single uniform plane of apposition. Typically, the surgeon will reduce the height of the posterior leaflet letting it serve as a “door-stop” for the anterior leaflet; the “height” refers to the distance from the base of the leaflet at the annulus to the leading edge of the leaflet at the free margin. Re-creating a uniform plane of apposition across the entire mitral valve eradicates the persistent leak and results in successful repair.

MITRAL VALVE REPAIR TECHNIQUES FOR ISOLATED POSTERIOR LEAFLET PROLAPSE

In patients with myxomatous disease of the mitral valve, more than 80% of the patients have pathoanatomy requiring repair of the posterior leaflet, predominantly P2, having either markedly elongated chords or actual rupture and flail chordae (Fig. 42.2A). There are many different techniques to repair this defect. Our preference is a limited resection of the flail segment, removing the minimal number of adjacent chordae and only as much of the supporting structures of the posterior leaflet as is necessary. A silk suture is placed at the middle of the offending segment and the area is excised in a trapezoidal shape, with the narrowest portion of the trapezoid at the annulus, to ensure maximum preservation of adjacent chordae. Once the flail segment is excised, there is a “drawing down” of the adjacent parts of P2 with two running 4-0 monofilament sutures, bringing the two remaining parts of the leaflet together (Fig. 42.2B–E). This is a “modified” leaflet advancement technique promoted by the lead author. The classic leaflet advancement technique popularized by Carpentier is shown in Figure 42.3. The drawback here is that one must incise the posterior leaflet completely off the annulus and then re-suture the leaflet back onto the annulus. As the two segments of the posterior leaflet are re-sutured, they are advanced medially toward the midpoint of the posterior annulus such that the two leaflet segments meet in the middle, reducing leaflet height in the process. Complete removal of the leaflet from the posterior annulus can be a daunting task for the less experienced surgeon. The “modified” advancement technique achieves the same goal as the classic Carpentier technique yet is more simplistic, less time-consuming, and more easily taught and adopted by cardiac surgeons with a more modest mitral valve case volume.

With either of these techniques, again, approximate the residual posterior leaflet segments to the annulus using two running 4-0 monofilament sutures advanced medially toward the center of the annulus. Then, with these sutures held on tension approximate the two residual leaflet segments to one another. With a double-armed 4-0-monofilament suture, begin at the leading edge of the leaflets and tie four knots such that equal lengths of the suture reside on each side of the knot. The two lengths of the suture are then run back toward the annulus suturing the leaflet edges together and tying a knot with the adjacent advancement sutures previously left untied and held on tension. The adjacent leaflet segments are brought together with a double over-and-over technique. From the leading edge of the leaflet, the first suture is a running mattress and the second suture is a simple over-and-over running stitch to prevent any chance of dehiscence. We do not use pledgets of any kind on the mitral valve leaflets, as they tend to produce scarring and may provide a site for potential thromboemboli. Once the posterior leaflet is refashioned, the valve is then tested for competency. Even without a supporting ring the valve is usually competent in 90% of patients at this point. An encircling annuloplasty ring or partial C-band is then fixated to the annulus to complete the repair. Of note, though we advocate the use of the “modified” advancement technique for its simplicity, in the case of true Barlow’s syndrome where all segments of the posterior leaflet are elongated, the classic Carpentier technique is required (Fig. 42.3), as the “drawing down” of P2 will not adequately reduce the height of the posterior leaflet sufficiently in this situation.

“Leaflet resection” is the time-honored traditional approach to mitral valve repair with isolated myxomatous posterior leaflet pathology. More recently, however, select surgical groups have endorsed a philosophy of “leaflet preservation.” This alternative approach to repairing the myxomatous prolapsing posterior leaflet implores maneuvers to preserve the excess tissue as opposed to resecting it. Polytetrafluoroethylene chordae, measured to the appropriate length, are anchored to the papillary muscle and sutured to the posterior leaflet. These strategically placed “neo chords” reduce the height of the posterior leaflet and restore the line of apposition with the anterior leaflet, heeding to the same basic principles followed for “leaflet resection” techniques. Historically, the biggest challenge to using neo chords has been constructing chords of the appropriate length. The work of Fried-rich Mohr in Leipzig, Germany, with the description of the Loop technique, using an intraoperative caliper to facilitate the construction of looped chords of precise length, has removed much of this guesswork and is credited for the increased popularity of this approach to posterior leaflet repair (Fig. 42.4).

Fig. 42.2. (A–E) Repair of the myxomatous mitral valve using the modified leaflet advancement technique. The figure illustrates the repair of a valve with ruptured chordae underlying the middle segment (P2) of the posterior leaflet.
An additional “leaflet preservation” technique advocated by the lead author and reserved for posterior leaflet prolapse without ruptured chordae is to simply fold over the redundant section of the posterior leaflet. A large needle double-arm 4-0 monofilament stitch inserted at the leading edge of the elongated segment is brought underneath the leaflet and directed back toward the annulus. The suture emerges at the annular attachment site and is securely tied in place. This simple technique, known as a “folding” or foldoplasty (Fig. 42.5), reduces the height of the posterior mitral leaflet by half. A single stitch is often all that is required; however, an additional two or three stitches placed in a similar manner may be necessary. An annuloplasty ring is then placed and a competent valve is achieved without any leaflet resection following a rather quick operation. This technique has been validated with published results to document its medium and long-term efficacy. Regardless of which technique one chooses, several simplified approaches are now available to reduce the posterior leaflet to normal height.

**SIZING AND FIXATION OF THE PROSTHETIC ANNULOPLASTY RING**

As previously mentioned, despite the apparent integrity of the valve after repairing the posterior mitral leaflet, because of the presence of annular distortion that will eventually lead to mitral valve leakage, the long-term competency of the valve repair is significantly enhanced with the placement of an annuloplasty ring. Sizing, placement, and fixation of the ring are key elements to remodeling the mitral annulus. As noted earlier, though there are many different rings, in our experience the most important aspect of the ring implantation is to find the size and shape that accomplishes the physiologic purposes of stabilizing the annulus. The keys to appropriate ring selection are shown in Figure 42.6. The importance of annuloplasty ring size and annuloplasty suture placement to properly fixate the ring cannot be overstated. An important aspect of ring placement is the identification of the trigone of the mitral valve anterior leaflet, which inextricably is the underside of the noncoronary leaflet of the aortic valve. This intertrigonal distance is extremely important to secure ring fixation. Whatever the type of the ring used, it must be anchored to the trigonal area, not to the commissural area. A C-band such as the Cosgrove–Edwards (Edwards Lifesciences Irvine, CA), Medtronic Future GC (Medtronic, Inc., Minneapolis, MN), or the partial Duran ring (Medtronic, Inc., Minneapolis, MN), have all been acceptable choices in our practice provided the anchoring sutures are properly placed in the trigonal area as shown. The commissural areas are mistaken for the trigones and used inappropriately as the anchor point for ring fixation in a surprising number of cases, resulting in early referral for reoperation.
Fig. 42.4. (A-D) Polytetrafluoroethylene chord insertion for mitral valve repair employing the Loop technique. Intraoperative calipers facilitate the construction of "premeasured" chords of precise length. The neochords are then sutured to the papillary muscles and affixed to the free edge of the prolapsing leaflet of interest.

Fig. 42.5. (A and B) Foldoplasty. A simple reparative technique that can be used when there is a prolapsing segment of redundant posterior leaflet and no ruptured chordae. A double-arm 4-0 monofilament suture is passed through the leading edge of the area in question and brought back underneath the leaflet to re-emerge at the annulus. The suture is then tied in a simple mattress configuration.
We place U stitches in the ends of the C-ring in the trilgona area well above the commissures as shown in Figure 42.6C. Rings can be implanted with running sutures; however, we prefer to use interrupted multifilament sutures with an emphasis on deep annular stitches that go into the ventricle and out again. In general, 9 to 12 sutures are sufficient to encircle ones prosthesis of choice for even the most dilated annulus. The sizing of the ring has been a source of confusion for many surgeons. The sizing is accomplished by measuring the length of the anterior leaflet. The intertrigonal distance can be very misleading, particularly in some patients in whom the anterior leaflet is extremely long but the intertrigonal distance is relatively short. Several reoperative referrals from other centers to the lead author have stemmed from the fact that the original rings were placed on the basis of the intertrigonal distance. This inevitably causes marked SAM because the ring is too small to accommodate the excess anterior leaflet tissue.

With the aid of transesophageal echocardiography, the length of the anterior leaflet can be measured and the ring size approximated before a surgical incision has even occurred. The measurement for the large myxomatous valve is usually at least 34 mm and in many situations will be as large as 45 mm. This is to emphasize the point that the larger sizes of the different annuloplasty rings are likely indicated when presented with myxomatous degenerated mitral valve in need of repair. Moreover, if for whatever reason one is unsure as to what size of ring to implant, it is generally better to upsise the ring rather than downsize the ring, as again, this will minimize the possibility of SAM of the anterior leaflet. Once the ring has been properly sized, sutures are placed in a mattress manner to fixate the ring to the annulus. The ring is then lowered to the annulus and the sutures are tied and cut. Importantly, many rings come with mandrels, which should be removed before the final three or four sutures are tied near one commissure or the other. This prevents unnecessary tension on the final sutures and protects against tissue tearing in the trilgona area. The valve is then tested. If the valve is competent the left atrium is closed, intracardiac air is evacuated with the intraoperative assistance of transesophageal echocardiography, and the patient is weaned from cardiopulmonary bypass.

**VARIATIONS ON A THEME**

There are a number of variations to the classic mitral valve repair techniques that should be in every surgeon’s armamentarium when considering mitral valve repair—specifically, (1) commissural prolapse, (2) cleft closures, (3) sub-leaflet calcification, and (4) intra-leaflet calcification.

Commissural prolapse with or without ruptured chords is one of the more simplistic defects to repair (Fig. 42.7). A leaflet segment with a ruptured chord at either the anterior lateral or posterior medial commissure can simply be obliterated without resection. The annulus of these patients is always so enlarged that a simple 4-0 monofilament mattress suture will obliterate the commissure and correct any leak resulting from the prolapsing chords at the site of interest. No further reparative techniques are necessary except for the annuloplasty ring. The area within the valve is so large that this obliteration makes little difference. It is a very quick repair and one that can be done with complete alacrity. In addition, a cleft in the posterior leaflet may sometimes be exaggerated when a ring is placed in a valve that is hugely dilated, some being as large as 60 mm. Testing of the valve will show a leak at such clefts. A simple 4-0 suture to elevate this area and keep it at the same plane as the adjacent segment is more than enough to extirpate this problem. This is usually accomplished after the ring is in place and valve competency has been tested.

Subannular calcium of the posterior leaflet can be a vexing problem. Carpenter has advocated a rather radical approach to this issue recommending complete removal of the calcified bar. This can lead to disassociation between the left atrium and the left ventricle requiring the difficult undertaking of reconstructing the ativoventricular groove. In the majority of cases, we would contend that this approach is unnecessarily aggressive and potentially dangerous. With careful debridement, one can remove an appropriate amount of calcium to allow a flexible repair. We have found subtotal excision of calcium to be satisfactory for leaflet coaptation in the majority of situations. In very rare circumstances, one may encounter a patient with ruptured chords of the posterior medial leaflet in the setting of an exorbitantly diffuse degree of calcification encasing the entire posterior annulus. A corrective repair is still feasible in this setting; however, the extensive calcium may prohibit insertion of an annuloplasty ring. Yet, if the calcium is so rigid as to prevent the insertion of an annuloplasty ring, it has inherently become a fixated structure that is unlikely to succumb to any further annular dilatation. This makes the role of a ring less vital to successful repair in this unique situation.

Finally, if there is calcium within the integrity of the mitral valve leaflets themselves, we believe that this is not likely to be repaired satisfactorily unless one can...
debride the calcium from the anterior leaflet. Calcified leaflets do not hold up in the long-term and are often the cause of reoperations. At times, a history of endocarditis will present as small residual calcific nodules embedded within the leaflets. These nodules are an exception to the rule as they are generally debrided with ease and leaflet flexibility restored. Otherwise, if leaflet flexibility cannot be retained it is our experience that achieving a long-lasting competent mitral valve repair will be difficult.

**MITRAL VALVE REPAIR TECHNIQUES IN THE PRESENCE OF ANTERIOR LEAFLET PATHOLOGY**

Many patients are referred to the surgeon with the diagnosis of “bileaflet prolapse” raising concern about reparability. There is no question that true anterior leaflet pathology makes a repair more complicated, but, in actual fact, many experienced mitral valve surgeons have noted that once a good posterior leaflet repair is done and the remodeling ring applied, “prolapse of the anterior leaflet” is not a factor. This can be determined by looking at chordal length upon examination of the valve. Thus, our approach to anterior leaflet pathology, unless ruptured chords of the anterior leaflet are present, is to perform the posterior leaflet repair, insert the appropriate sized annuloplasty ring, and only then see what else must be done. The expression “less is more” is never better attributed to an operation than here because in the vast majority of patients, the prolapse in the anterior leaflet is rather modest and it is the posterior leaflet pathology that is the predominant cause for the regurgitant valve.

When it is absolutely required to lower the height of the anterior leaflet or there are ruptured anterior leaflet chordae, it can be accomplished in a few relatively straightforward ways. The first option is to insert polytetrafluoroethylene chords into the anterior leaflet in the same manner as was discussed above for posterior leaflet pathology. Though the use of neochords has gained increased popularity for posterior pathology in recent years due to the simplification of neochord measurements, neochords were first introduced more than 20 years ago by Tirone David in Toronto and Robert Frater in New York. To be precise, in the original descriptions, neochord placement was primarily promoted as a corrective technique for anterior leaflet pathology. The more traditional approach...
to neochord placement is to determine neochord length “after” attachment of the neochord to the papillary muscle. Once the neochord is secured to the papillary muscle with a double-arm suture, the two ends of the suture are brought up through the underside of the leaflet at the leading edge left untied. This is different than the Loop technique, where neochord length has been predetermined and constructed at a side table “before” attachment to the papillary muscle based on caliper measurements. With the traditional technique, the neochord is set to the appropriate length by tying the sutures at the leading edge of the leaflet with the left ventricle fully distended with saline solution. The surgeon then determines the height at which to secure the knot at the leading edge, which then sets neochord height, so that the knot occurs at the exact point where coaptation with the posterior leaflet is achieved (Fig. 42.8). Another technique first popularized by Duran is the “flip over” technique (Fig. 42.9). Here the surgeon incises a noninvolved segment of posterior leaflet with normal chordae and brings this across to the anterior leaflet of the mitral valve. This healthy posterior mitral leaflet segment is “flipped over” onto the anterior leaflet and becomes the supporting chordae for the affected area of the anterior leaflet. This can work well in experienced hands but we have not used this technique because we prefer not to disfigure a normal posterior leaflet. A final option that may be considered is triangular resection of the anterior leaflet (Fig. 42.10). Though we do not use this technique, as it is our general contention that anterior leaflet resection should be avoided, heeding the advice of Dr. Carpentier who professed that anterior leaflet resection can distort the leaflet and impede coaptation, we acknowledge the work of Irving Kron, coeditor of this textbook. Dr. Kron has utilized triangular resection for both anterior and posterior pathologies, and in his experience results have been excellent with this technique.

**SYSTOLIC ANTERIOR MOTION**

SAM of the mitral valve is a concern for every patient undergoing mitral valve repair. SAM is the obstruction of the left ventricular outflow tract caused by the paradoxical movement of a large anterior leaflet into the outflow tract during systole. A thickened ventricular septum can also be a contributing factor. This was seen much more frequently with rigid encircling rings or when the height of the posterior leaflet was inadequately reduced. In most instances, the chordal structure of the mitral valve is able to prevent SAM. Nevertheless, the incidence of SAM is still between 2% and 16% in reported series and a problem that all surgeons are likely to encounter at some point. Cardiac anesthesiologist and/or cardiologists who do intraoperative echocardiography are quite expert at predicting which patients are at risk for SAM even before an incision is made. Echocardiographic parameters predictive of SAM that the surgeon should be aware of are (1) prerepair anterior to posterior leaflet ratio <1.4 and (2) the so-called C-sept distance <2.6 cm (“C-sept” refers to the distance from the line of mitral leaflet coaptation to the interventricular septum). In addition, excessive leaflet slack postrepair should alert the surgeon to a high likelihood of SAM. This occurs when there is an enormously elongated and enlarged anterior leaflet with a profound dilation of the annulus. When attempting to size the annuloplasty ring to the anterior leaflet, the annuloplastic ring necessary to properly fan out the leaflet will be far larger than the largest commercially available rings, as the maximum size available in North America is only 38 to 40 mm.

A technique that we have found very effective in this scenario, where a large myxomatous mitral valve makes SAM a major concern, is the edge-to-edge technique (Fig. 42.11). The edge-to-edge repair in this situation is very helpful when all other attempts to reduce SAM have failed. In our practice, this entails a figure-of-eight stitch with a multifilament suture (for strength), as opposed to a monofilament suture. We have also used this technique in patients with severely reduced left ventricular function and prolapsed valves with ruptured chords of the anterior leaflet. This is a short operation and a real-time saving maneuver. We do this after the ring is in place and all of the reparative techniques are done so as to align the anterior leaflet in the right position to be approximated. We also use a caliper to make sure that the two side orifices are large enough to allow a relatively normal pressure gradient between the left atrium and left ventricle. Ideally, the two orifices should have a 2 cm × 2 cm area of clearance. This technique works very well for patient with a prolapsed myxomatous valve but we never use this technique in patients with ischemic mitral valve disease or any other condition where the valve is relatively small due to concerns for mitral stenosis.

Mid- and late-term studies from our institution with the edge-to-edge repair when used solely for the prevention of SAM in large prolapsed valves have shown excellent repair durability, SAM prevention to be maintained, and no significant stenosis.
to have occurred. If, however, the edge-to-edge repair is used as a “bail-out” in conjunction with other surgical techniques for complex forms of mitral repair, where the initial techniques did not achieve an adequate repair necessitating the edge-to-edge at the end of the procedure, the results are not nearly as good and the potential for recurrent regurgitation or stenosis is fairly significant. Triangular resection is another choice that may be used for SAM prevention though we feel the edge-to-edge repair to be a better option.

Finally, the ultimate judgment regarding the success of one's mitral valve repair is
Section II: Adult Cardiac Surgery

Fig. 42.11. The edge to edge technique. This is an adjunctive technique utilizing patients with a high propensity for systolic anterior motion based on pre-bypass echocardiographic findings or post-repair intra-operative systolic anterior motion. (A) Replacement of a figure of 8 suture at the mid-portion of the anterior and posterior leaflet and (B) shows the figure of 8 multi-filament suture after tying and knot cutting to create a double orifice valve.

determined using the postcardiopulmonary bypass transesophageal echocardiogram. Transesophageal echocardiography is absolutely necessary in every patient undergoing mitral valve surgery. In patients with contraindications to transesophageal probe insertion, we employ epicardial echocardiography with close collaboration from anesthesia. Should there be moderate residual mitral regurgitation this has to be addressed. After a suitable period of reperfusion, one should go back on cardiopulmonary bypass and look at the repaired valve to determine where one can improve the coaptation line and reduce the residual mitral regurgitation. There are now 20- and 30-year outcome data available for reparative procedures on the mitral valve from select centers including our own, the Cleveland Clinic and Dr. Carpentier's personal series. The probability of a re-repair at 10 years should be <10% and at 20 years <15%. Mastery of the simplistic techniques that have been discussed thus far will provide the surgeon with an armamentarium necessary to repair the vast majority of myxomatous degenerated valves that present in clinical practice. These simple techniques provide excellent long-term results. Though patients will present with the same underlying degenerative process the exact mechanism for their regurgitation will vary. The ability to incorporate the many options discussed above allows the surgeon flexibility
so as to treat every patient individually and adjust the corrective repair to fit each individual patient’s needs.

MITRAL VALVE RE-REPAIR OF THE MYXOMATOUS MITRAL VALVE

Re-repair of the myxomatous mitral valve after a previous repair can be accomplished. A review of the re-repairable cases of the mitral valve from our series of 2000 mitral valve repairs has indicated five important causes of repair failure: (1) progression of disease with rupture of additional chords within the mitral valve apparatus unrelated to the previous repair, (2) failure to lower the height of the posterior leaflet, (3) failure to lower the height of the anterior leaflet so bulging of the anterior leaflet persists, (4) failure to use an annuloplasty ring, and (5) insertion of too small an annuloplasty ring largely due to inappropriate sizing with intertrigonal distance utilized instead of using the size of the anterior leaflet. This latter issue is probably the most common cause of mitral valve re-repair in our experience. When this is the case, where at the original valve repair the valve was large and an undersized ring was used related to the intertrigonal distance, simply inserting a new larger ring often resolves the problem. If, however, there is an accumulation of calcium on the valve, either because it was left untreated from the initial operation or it has accrued with time, valve replacement is required.

CONCLUDING REMARKS

The clinical outcomes of the lead author’s 40-year experience with mitral valve repair for all etiologies of mitral disease have been summarized in a recent presentation to the American Association for Thoracic Surgery. In comparison to other etiologic conditions for mitral regurgitation, surgical outcomes with myxomatous mitral valve repair are unmatched. Postrepair survival endures the longest, and the incident of recurrent regurgitation is the lowest (Fig. 42.12). Though these differences are in many respects attributable to the different patient populations and their varied comorbidities, with regard to the pathology, the results are a shining testament to the effectiveness of reparative surgery for myxomatous disease.

To close, though we have expounded on the techniques to repair the myxomatous valve once it has been exposed, it is worth mentioning the varied surgical options available to gain exposure. Most important, a full median sternotomy for maximal exposure is always an appropriate option. A technically skilled repair is paramount and takes precedence above anything else. However, it is noteworthy to mention that many of these mitral valve repair techniques are amenable to less invasive surgical methods. Our personal preference is a lower hemisternotomy. Late clinical and echocardiographic data from our institution with this approach have validated its safety and efficacy. Still, other groups have preferentially used a right mini-thoracotomy, thorascopic techniques, or robotic assistance, with equally impressive results. Regardless of which approach one chooses, adhering to the simple techniques discussed in this chapter will go far to ensure excellent outcomes in clinical practice.

SUGGESTED READINGS

Dr. Cohn and Dr. McClure’s chapter on mitral valve repair is about as comprehensive approach as one can imagine. Dr. Cohn’s 40-year experience with mitral valve disease certainly gives him expertise to have dealt with every type of mitral valve pathology. All the basic principles are discussed and the authors have alluded that many techniques truly work. The most important concept the authors have emphasized is that mitral valves must be repaired. I have heard Dr. Cohn state multiple times that sliding plasty may have been the worst thing to happen to mitral valve repair. The techniques obviously are excellent but the perceived complexity pushes inexperienced surgeons to end up replacing the valve.

I agree with most of the techniques elaborated on by the authors. I think the limited resection of the posterior leaflet mitral valve is an outstanding technique and allows for confident mitral valve repair in the majority of cases. I very much admire the approach to cords then there is rupture involving the same sections of anterior and posterior leaflets. Dr. Cohn’s technique of simply closing this adjoining sections of leaflet with a suture adding a ring does work and makes a complex situation fairly simple.

In our practice, we have not been as concerned with the height of the posterior leaflet. This is a classic Carpentier concept. I think the solution for this problem is just to use bigger rings. Since we have begun using larger rings in our practice, we have almost never seen SAM that was a major issue in the early days of mitral valve repair. Finally, I agree with the concept of either limited resection or chordal replacement for annular leaflet pathology. The bottom line is that all degenerative disease is repairable and can be repaired. The most certain way to harm a patient in the long term is to replace a repairable valve.

ILK
Mitral Valve Repair—Robotic Minimally Invasive
Alan P. Kypson, L. Wiley Nifong, and W. Randolph Chitwood

INTRODUCTION
Bailey (1951), Harken (1953), Davila (1954), and Glover (1956) made early attempts to repair mitral valves. These methods are usually related to epicardial reduction of the mitral annulus size or reducing a regurgitant orifice by “plugging” with a cone-shaped prosthesis. Later, Kay (1961), Woller (1962), and Reed (1965) developed intracardiac suture annuloplasties to reduce the posterior mitral annulus length, thereby improving leaflet coaptation. McGoon (1960) performed the first repairs for ruptured chordae tendineae, and Austin (1963) first replaced a mitral valve for a papillary muscle rupture. The advent of mechanical valves impeded the progress of mitral valve repair surgery until the early 1970s, when Carpentier and Duran pioneered novel reconstructive techniques. Despite mitral valve repair successes in Europe, skepticism pervaded U.S. surgeons until Carpentier showed in 1983 excellent long-term repair results. These outcomes were based on his elucidation of the functional anatomy in insufficient mitral valves and the development of reproducible repair methods. By the late 1980s, numerous published reports from other centers validated the long-term durability of repairs, freedom from anticoagulation, and decreased mortality compared with mitral replacements.

Mitral valve surgery has been performed traditionally through a median sternotomy, which provides generous operative exposure and global cardiac access. However, during the past 15 years, improvements in instruments and endoscopes, as well as patient demand, have resulted in a substantial increase in minimally invasive general and subspecialty surgical procedures. Endovascular port-access technology first enabled less invasive surgical approaches to mitral valve surgery that avoided a median sternotomy. Advances in closed-chest cardiopulmonary bypass and myocardial protection, as well as intracardiac visualization, instrumentation, and robotic telemanipulation all have hastened a shift toward efficient and safe minimally endoscopic cardiac surgery. Today, mitral valve surgery, done through small incisions using robotic assistance, has become standard practice for an increasing number of cardiac surgeons and centers.

ROBOTIC TECHNOLOGY
Computer-assisted robotic cardiac surgery platforms have been developed to facilitate surgeon hand motions in limited operating spaces. These devices offer advantages of improved access, magnified vision, and stabilized instrumentation implementation. Six degrees of freedom are required to allow any free orientation of instruments in any space. Endoscopic instrumentation with four degrees of freedom reduces the dexterity significantly that is needed for delicate cardiac surgical procedures. Furthermore, the loss of depth perception with two-dimensional video monitors further increases operative difficulty. Computer-enhanced (robotic) instrumentation systems overcome these and other limitations. In fact, their impact has been so great that a paradigm shift for both the patient and the surgeon has changed dramatically.

Robotic systems consist of telemanipulators with end-effectors, or microinstruments, being controlled remotely from a console. The da Vinci®S system (Intuitive Surgical, Mountain View, CA) is composed of a surgeon console, an instrument cart with four integrated arms, and a visioning platform (Fig. 43.1A and 43.1B). The operative console is removed physically from the patient and allows the surgeon to sit comfortably, immersed into the operative field using high-definition three-dimensional imaging. Digital images are translated to analog natural depth perception with high-power magnification (10×). Finger and wrist movements are registered through sensors and translated into motion-scaled tremor-free movements that avoid the fulcrum effect and instrument shaft shear forces, which are common to endoscopic instrumentation. Wrist-like articulations at the ends of microinstruments bring the pivoting action to the plane of the operative field, improving dexterity in tight spaces and allowing truly ambidextrous suture placement. A clutching mechanism enables constant readjustment of surgeon hand positions that are necessary to maintain an optimal ergonomic attitude with respect to the visual field.

EVALUATION OF MINIMALLY INVASIVE MITRAL VALVE SURGERY
Initially, minimally invasive mitral valve surgery was based on modifications of previously used incisions and performed under direct vision. Minimal access incisions provided adequate direct vision mitral valve exposure, and surgeons showed that mitral valve operations could be done as safely and precisely as done through a larger incision. Large series by Cohn and Cosgrove showed initially that surgical mortality (1% to 3%) and morbidity were comparable to those of conventional mitral surgery. By employing familiar approaches and relying on direct vision, the initial steps in minimally invasive mitral surgery became less daunting.

With acquired experience, a shift from direct vision to video-assistance occurred and operations began to be performed using secondary vision. In 1996, Carpentier performed the first video-assisted mitral valve repair through a right minithoracotomy using ventricular fibrillation. In 1997, Chitwood described the first mitral valve replacement using videoscopic vision. The operation was done using a 6-cm right anterior mini-thoracotomy, peripheral cardiopulmonary bypass, and a percutaneous transthoracic aortic cross-clamp, and retrograde cardioplegia. In 1998, Mohr reported the Leipzig Heart Center experience of 51 minimally invasive mitral operations done using port-access technology.
Section II: Adult Cardiac Surgery

Fig. 43.1. (A) da Vinci™ S Robotic Tele-manipulation System: The operative console where the surgeon is seated. (B) da Vinci™ S Robotic Tele-manipulation System: The instrument cart with four arms.

Within a week, Mohr performed five mitral repairs with the same device. In May 2000, our group performed the first complete mitral valve repair in North America using the da Vinci™ system. In that operation, a large P₂ trapezoidal resection was done with the defect closed using multiple interrupted sutures, followed by implantation of an annuloplasty band. Robotic technology has progressed to a point where at our center totally endoscopic mitral procedures have become routine for patients with isolated mitral valve pathology.

**PATIENT SELECTION**

All patients with isolated degenerative mitral valve disease are considered for a robotic mitral repair. Complex mitral disease is always approached with the techniques described herein. Contraindications include a prior right thoracotomy and circumferential annular calcification (Table 43.1). Moderate annular calcification alone does not preclude patients from undergoing a minimally invasive approach. However, extensive “bar” calcification remains for us a definite contraindication.

Patients with poor lung function undergo pulmonary testing to ascertain whether they will tolerate single-lung ventilation. Should patients not be able to tolerate isolated lung ventilation, cardiopulmonary bypass is instituted earlier for intrathoracic access. The transesophageal echocardiogram (TEE) remains the gold standard for perioperative planning. It is important to correlate the dynamic echocardiographic anatomy with both the Carpentier functional class and the intraoperative pathology. In patients over 40 years old, and/or with a strong family history and/or symptoms of coronary disease angiography is done preoperatively.

**Table 43.1** Robotic Mitral Surgery Exclusion Criteria

- Previous right thoracotomy
- Renal failure
- Liver dysfunction
- Bleeding disorders
- Pulmonary hypertension (PAS >60 Torr)
- Significant aortic or tricuspid valve disease
- Coronary artery disease requiring surgery
- Recent myocardial ischemia (<30 d)
- Recent stroke (<30 d)
- Severely calcified mitral valve annulus
Anesthesia and Monitoring

To provide single-lung ventilation, either a dual lumen endotracheal tube or bronchial blocker is used. Hemodynamic monitoring is done with a radial arterial line and a pulmonary artery catheter. For superior vena caval (SVC) drainage the right jugular vein is cannulated percutaneously with either a 15F or 17F thin-walled Biomedicus™ (Medtronic, Inc., Minneapolis, MN) arterial cannula using the Seldinger guide-wire technique. This is performed before surgical draping by our anesthesiology colleagues.

Three-dimensional TEE is used to evaluate cannula placement, annular size and quality, the leaflet coaptation plane, leaflet length, and the subvalvular mitral apparatus. The intensity and direction of regurgitant jets help us to determine the significance of leaflet pathology. The transgastric view is very helpful for defining precisely which mitral segments need correction. Currently, we select the annuloplasty band size based on TEE measurements of the anterior leaflet length, annular diameter, and septal thickness. Patient-side surgeon comfort and direct vision are most important when gaining ideal intracardiac access for the placement of the robotic instrument arms and the camera. Table-side surgeon long focal-length loupes (3.5×) are most helpful for early preparation as well as passing sutures and specimens through the 3-cm incision during a da Vinci™ repair.

Operative Techniques and Technology

Patients are prepared with the right thorax elevated 30 degrees on a towel roll and the right arm secured by the side. A 3-cm mini-thoracotomy incision is made in the sub-mammary fold in the anterior axillary line. After right lung deflation, the pectorals muscle is spared, and the fourth intercostal space is entered. Pericardial exposure is obtained without rib resection or division, and a soft tissue retractor (Applied Medical Resources Corp., Rancho Santa Margarita, CA) is inserted to displace the skin, fat, and muscle layers, leaving an oval space between the ribs. If the right hemi-diaphragm obstructs the operative field, a suture is placed in the central tendon and pulled through the chest wall with a “crochet hook” instrument, retracted, and secured. The pericardium is opened 2 cm anterior to the phrenic nerve and extended toward the inferior vena cava (IVC) and aortic reflections. Transthoracic pericardial retraction sutures should be placed near the SVC reflection and the atrio-IVC juncture to distract the posterior (dorsal) pericardial edge laterally. To minimize intracardiac air retention, a 14 G catheter is placed through the chest wall for continuous carbon dioxide insufflation (2 to 3 L/min). Instrument arm trocars are then placed through the third and fifth intercostal spaces and sighted to be in direct line with the mitral annulus (Fig. 43.2). It is important to maintain at least 8 to 10 cm between these arms to avoid intracardiac instrument collisions during the repair.

For cardiopulmonary cannulation, an oblique 2 cm right groin incision is made and superficial purse-string sutures are placed in both the femoral artery and vein. Then, coaxial dilators are introduced over a guide wire. Under TEE guidance, a 22F femoral vein venous cannula (Estech, San Ramon, CA) is positioned in the central right atrium. This cannula should not be suture-anchored, as intraoperative manipulation may be needed to provide optimal venous return. If SVC drainage is not possible because of patient small body habitus, a single 23/25F venous cannula (Estech) should be positioned in the SVC. By the same method, the femoral artery is cannulated with either a 17F or 19F Biomedicus™ arterial cannula. Using (kinetic-assisted) suction venous drainage, patients are cooled to 28°C systemically. Thereafter, an ascending aortic antegrade cardioplegia/vent catheter is placed just distal to the right coronary ostium. This position allows deployment of the transthoracic clamp without crowding the cardioplegia/vent catheter. Retrograde coronary sinus catheters also can be placed either across the right atrial wall or from the jugular vein and positioned using TEE.

The intratrarial (Waterston’s, Sondergaard’s) groove is dissected minimally and the oblique sinus is opened behind the IVC. To occlude the aorta under either endoscopic or direct visual direction, the transthoracic aortic clamp (Scanlan, Inc., Minneapolis, MN) is placed through the second interspace in the mid-axillary line with the posterior fixed-time directed through the transverse sinus, passing posterior (dorsal) to the ascending aorta. Care must be taken to avoid injury to the right pulmonary artery, the left atrial appendage, or the left main coronary artery. After the clamp is applied, the heart is arrested either with antegrade and/or retrograde cold blood cardioplegia.

A short left atriotomy is made inferior to the right superior pulmonary vein with extension toward and inferiorly behind the IVC. The arm of a percutaneous left atrial retractor is positioned just lateral to the sternal edge and medial to the incision, avoiding internal mammary vessels (Fig. 43.2). The dynamic retractor blade is inserted into the left atriotomy. Ventral retraction should elevate the interatrial septum to provide optimal mitral valve exposure. A left superior pulmonary vein sump sucker scavenges residual left atrial blood. Instrument arms are then passed through trocars and positioned in the left atrium, and the three-dimensional endoscope is positioned through the superior part of the incision. Valve function is evaluated using cold saline injections. The tableside surgeon is responsible for exchanging the various microtipped instruments. Standard reconstructive methods have been used in all of our da Vinci™ mitral valve repairs (Table 43.2). We are comfortable in performing leaflet resections, sliding-plastics, chordal transfers, chordal replacements, as well as annuloplasties. We consider patients with Barlow’s bileaflet disease as optimal for robotic repairs.

MITRAL VALVE DISEASE AND REPAIR TECHNIQUES

Degenerative Mitral Disease

At our center, robotic instruments and techniques are used to repair degenerative (myxomatous) mitral valves. Classic features of this disease include leaflet prolapse and annular dilatation. Carpentier’s functional classification of mitral insufficiency is based on leaflet motion characteristics. Insufficiency with normal leaflet motion is Type 1, with exaggerated (prolapse) leaflet motion is Type 2, and with restricted leaflet motion Type 3. Most common robotic mitral repairs are amenable to Type 1 and 2 pathologies. Chordae tendineae may be thinned, elongated, and/or ruptured. Posterior (P) chordal rupture and/or elongation with a dilated annulus are the most common problems that we repair. In the past, only symptomatic patients with 3+ or 4+ mitral regurgitation and ruptured/elongated posterior leaflet chords have been referred for surgery. With the advent of safe, effective minimally invasive and robotic mitral surgery, more asymptomatic...
patients with moderate-to-severe regurgitation are being referred earlier. This is especially true for patients who have developed any left ventricular functional impairment or dilatation. Moreover, the presence of early atrial fibrillation indicates significant detrimental changes in progression of valvular disease. To improve long-term survival, there is clear evidence that patients with ruptured chords and a flail leaflet segment should be repaired. In asymptomatic patients, newer indications are predicated on preventing ventricular dysfunction, left atrial dilatation, and the development of atrial fibrillation.

**Posterior Leaflet Prolapse**

As mentioned, posterior leaflet prolapse/flail occurs most commonly. Robotic micro scissors and atraumatic tissue forceps are used for leaflet resections. Robotic needle holders should never be used to grasp delicate leaflet and chordal tissues. Posterior leaflet prolapse is treated either by triangular, trapezoidal, or quadrangular resection of the diseased chordal leaflet segment (Fig. 43.3). We limit the length of the annular gap, especially in patients who do not require a sliding leaflet plasty to reduce the posterior leaflet height. Any annular defect is then reduced robotically using 2-0 Ticron.

---

**Fig. 43.2.** Robotic posterior leaflet resection. A trapezoidal incision is created in P₂ (A and B) and annular compression sutures are placed (C). The leading edges of the remaining leaflet are then brought together using interrupted 5-0 Cardionyl (D). The repair receives a band annuloplasty (E).

Figure-of-eight sutures. Residual leaflet edges are approximated with 4-0 or 5-0 Cardionyl (Peters, Inc., Paris, France) interrupted sutures. This monofilament suture has less memory and more strength than polypropylene material. In robotic operations, we have most frequently used the Cosgrove–Edwards™ annuloplasty band (Edwards Lifesciences, Irvine, CA), which is placed between each fibrous trigone using either tied 2-0 braided sutures, nitinol U-clips™ (Medtronic, Inc., Minneapolis, MN), or the Cor-Knot™ device (LSI Solutions, Inc., Victor, NY) (Fig. 43.4). Recently, the nitinol U-clips™ have been taken off of the market.

When we are concerned about systolic anterior motion (SAM) of the anterior leaflet, a sliding leaflet repair is indicated and can be performed with the da Vinci™ system. Postrepair SAM can develop in patients with excess posterior leaflet tissue (posterior height >1.5 cm), a long anterior leaflet (>34 mm), left ventricular outflow-track septal hypertrophy, and in the presence of an acute angle (<120 degrees) between the aortic and mitral annulus valve planes. Moreover, SAM can be caused by an undersized annuloplasty ring or band. It is not true that SAM can never develop when using a flexible ring or inter-trigonal annuloplasty band. The SAM...
potential is created when the mitral reconstruction forces the middle or basal anterior leaflet to coapt with the tip of posterior leaflet. During systole, the anterior leaflet tip moves toward the septum and the outflow-jet “lift” causes unphysiologic leaflet displacement toward the outflow tract septum. This displacement can open the leaflet coaptation point, causing significant residual mitral regurgitation. Insufficiency can occur even with a competent valve “saline test” in the arrested heart. It makes sense that ventricular hypertrophy and inotropic support can decrease the leaflet–septum distance thus increasing SAM and the outflow tract pressure gradient.

The purpose of the sliding leaflet repair (Fig. 43.5) is to reduce the height of the posterior leaflet, which moves the anterior leaflet coaptation point more posterior.
Chordal Transfers and Prosthetic Chord Replacements

Using da Vinci™, we prefer to reduce the anterior leaflet to the coaptation plane by either transferring marginal or large basal chords. The three-dimensional high magnification camera and microscissors allow us to detach anterior leaflet basal chords and transfer them directly to the flail edge of the leaflet. Moreover, posterior leaflet primary chordae can be transposed to the unsupported region of the anterior leaflet. Many prolapsing or flail posterior leaflet segments still have some good, thick chords, and these can be transferred anteriorly with a patch of leaflet for firm anchorage. Generally, by swinging either basal (secondary) anterior leaflet or residual posterior leaflet primary chords to the anterior leaflet edge, the radial movement geometrically reduces the anterior leaflet prolapse. The defect in the posterior leaflet is repaired as described for a standard quadrangular resection (Fig. 43.6). For significant anterior leaflet prolapsed, multiple chords

Fig. 43.5. Gore-Tex™ neochords for anterior leaflet prolapse (A). Here, a flail anterior chorda is being replaced. A 4-0 Gore-Tex™ is passed in "criss-cross" manner through a viable papillary muscle head. Sutures are passed through the edge of the leaflet and looped around the edge to reperforate the leaflet (B). The suture is then tied while we perform the saline test and remeasure chordal lengths to ensure perfect leaflet coaptation (C and D).

Anterior Leaflet Prolapse

A variety of techniques have been used to repair mitral anterior leaflet prolapse. Currently, the most common methods include chordal transfers and prosthetic chord replacements. Using da Vinci™, we prefer to reduce the anterior leaflet to the coaptation plane by either transferring marginal or large basal chords. The three-dimensional high magnification camera and microscissors allow us to detach anterior leaflet basal chords and transfer them directly to the flail edge of the leaflet. Moreover, posterior leaflet primary chordae can be transposed to the unsupported region of the anterior leaflet. Many prolapsing or flail posterior leaflet segments still have some good, thick chords, and these can be transferred anteriorly with a patch of leaflet for firm anchorage. Generally, by swinging either basal (secondary) anterior leaflet or residual posterior leaflet primary chords to the anterior leaflet edge, the radial movement geometrically reduces the anterior leaflet prolapse. The defect in the posterior leaflet is repaired as described for a standard quadrangular resection (Fig. 43.6). For significant anterior leaflet prolapsed, multiple chords...
must be transferred with the saline test used to confirm appropriate edge reduction. Because of the lack of tremor, precise visioning system, and microinstruments, with improved robotic access it is much easier to transfer chords using da Vinci™ system than operating through a sternotomy using conventional instruments and direct vision.

Our second choice for reduction of anterior leaflet prolapse is by using chordal replacements with 5-0 or 4-0 PTFE suture (Gore-tex™, Gore, Inc., Phoenix, AZ). Using the da Vinci™ system, papillary muscle access is magnificent. A short (16 cm) double armed 4-0 Gore-Tex™ suture is passed in a figure-of-eight manner through the papillary muscle fibrous head.

**Fig. 43.6.** Robotic Barlow’s repair. A segment of $P_2$ is resected and transferred to the underside of $A_2$ (A and B). Compression sutures are placed in the annulus and tied immediately (C). A running sliding annuloplasty is often performed (D). Final repair (E).
Thereafter, the needles are passed through the leaflet edge at the rupture/prolapse site. Then, the same suture is looped around the coapting edge and back through the leaflet, creating a “locking loop” (Fig. 43.7). The second chord is placed in a similar manner with a 3-mm gap between the sutures. After chordal length adjustment and before the two chords are tied with robotic instruments, saline testing is done to assure optimal neochordal length and optimal leaflet coaptation.

In all of our mitral valve repairs, we have abandoned Carpentier’s method of chordal shortening by tucking an elongated chord into a papillary trench. Simpler methods have been very satisfactory and reports of late chordal ruptures with the trench method have shifted our focus from correction at the papillary end to the leaflet end. Robotic methods lend themselves better to the methods described herein, and to date we have had no late ruptures in chordal transfers or replacements. In severe Barlow’s bileaflet disease, we generally transfer a long strip of chord-bearing posterior leaflet (usually P3) to prolapsing segments of A1–A3. Then the resected part of the posterior leaflet is closed using the reducing sliding plasty and commissural prolapse is corrected with the edge-to-edge method. Of course, a properly sized annuloplasty band or ring is selected to complete the robotic repair.

**Annuloplasty**

Annular dilatation is present in most patients with degenerative mitral disease. An annuloplasty is performed in conjunction with all repairs to restore the native geometry, reduce the annular size, prevent further dilatation, and reinforce the repair. Reducing the anterior–posterior annular diameter increases the leaflet coaptation surface. We select an annuloplasty support prosthesis that is either flexible or rigid and surrounds the mitral annulus either completely or incompletely. The latter notion suggests that the mitral-aortic curtain or central fibrous body of the heart, which extends between the fibrous trigones,
Fig. 43.7. Robotic suture placement for mitral annuloplasty (A and B). Twelve-centimeter sutures are used and tied serially (C).

is nonmuscular and does not dilate in patients with degenerative mitral disease. The Cosgrove–Edwards™ (Edwards Lifesciences, Irvine, CA) annuloplasty band is anchored at each trigone and for the remaining muscular annulus both reduces and remodels the valve geometry. An ideal prosthesis should be flexible, soft, and easy to handle with robotic instruments. To date, no complete ring satisfies these requirements, and the Cosgrove–Edwards™ band has served well for our repairs as the major etiology has been from degenerative causes and not ischemic deformation.

Short (14 cm) double armed 2-0 sutures currently are unavailable and therefore, the band is attached using the single-arm method shown. Initially, sutures are placed into each fibrous trigone to aid in exposure. Also, we detach the band from the template in order to manipulate it in the confined interatrial space. Without careful implantation, this could be suboptimal as nonlinear placement of sutures or variations in spacing can cause kinking of the band and annular asymmetry. To obviate kinking and uniform implantation, the band is first anchored to the right fibrous trigone with measured suture placement proceeding clockwise. The last two sutures at the anterior commissure and left fibrous trigone are placed before tying either. Care must be taken in this region to avoid injury to the aortic root and the circumflex coronary artery. Good anchoring bites can be obtained here but the needle must remain perpendicular to the annulus and not tangential toward the aorta or circumflex region. The da Vinci™ system high-definition camera enables precise placement of deep precise bites along the annulus. From our experimental studies we have seen adequate annular compression, ease of placement, and band security to be optimal using either suture-tying or automatic securing clips. Using the Core-knot™ clip device, recently we have found that our band implantation times have decreased significantly compared with the suture technique described.

**CLINICAL OUTCOMES**

Currently, we have performed over 700 robotic mitral valve repairs with the daVinci™ system. Our training program has trained over 400 surgeons in mitral repair surgery using da Vinci™ system, and many of these groups are already successfully doing repairs.
da Vinci™ Robotic Mitral Valve Repairs

In the first Food and Drug Administration (FDA) safety and efficacy trial of robotic mitral valve repair, quadrangular leaflet resections, leaflet sliding plasties, chord transfers, polytetrafluoroethylene chord replacements, reduction annuloplasties, and annuloplasty band insertions were performed in 20 patients at East Carolina University. The first overall cardiac arrest times were long at 150 minutes but only were 52 minutes for leaflet repairs. Moreover, it took an additional 42 minutes to anchor the Cosgrove-Edwards™ annuloplasty bands (mean 7.5 sutures). The operative times varied long but the results were good, and there were no device-related few procedure-related complications. The average postoperative stay was 4 days (3 to 7 days). At 3-month follow-up, echocardiographic studies revealed nothing more than trace mitral regurgitation in these patients. Moreover, all patients returned to normal activity 1 month following surgery.

A subsequent multicenter, phase II FDA trial studied 112 da Vinci™ patients operated in 10 U.S. centers. Again, repairs included quadrangular resections, sliding plasties, edge-to-edge approximations, and both chordal transfers and replacements. Leaflet repair and annuloplasty times had fallen to 37 and 39 minutes, respectively, compared with phase I trial outcomes. Aortic cross-clamp and cardiopulmonary bypass times averaged 2.1 and 2.8 hours, respectively. There were little differences in operative times between centers. One-month follow-up by transthoracic echocardiography revealed that nine patients (8.0%) had grade 2 mitral regurgitation and six (5.4%) of these had reoperations. Although the reoperative rate was disturbing, failed repairs were distributed evenly across the overall cohort and some centers had performed <10 robotic operations. There were no deaths, strokes, or device-related complications. This study demonstrated that multiple surgical teams could perform robotic mitral valve surgery safely early in the development of these techniques, albeit with a learning curve as far as operative times and repair results. Based on these two studies, the da Vinci™ robotic surgical device was FDA approved in November of 2002 for intracardiac use in the United States.

Learning curve data from our first 38 da Vinci™ mitral repairs were encouraging. Patients were evaluated in two cohorts: Early (N=19) and Late (N=19) follow-up. Operative times were chronicled starting after the robot was positioned to begin the repair. Total robotic operating times decreased from 19 to 15 hours (P = 0.002), respectively, between the two groups. Concomitantly, leaflet repair times fell from 1.0 to 0.6 hours (P = 0.004), respectively. Both cross-clamp and bypass times decreased significantly with experience as well. More recently, a learning curve analysis of over 450 robotic mitral valve repairs performed at our institution demonstrated a logarithmic learning curve, with a learning percentage of 95%. Multiple regression analysis defined significant variables that affected total robotic operative times and included: type of repair, band size, use of clips alone for band implanta­tion, and the presence of a postgraduate fellow at bedside.

To date, we have completed over 700 robotic mitral valve repairs with the da Vinci™ system and have published results on the first 300. There was a 0.7% 30-day mortality and a 2.0% late mortality. No patients underwent valve replacement or conversion to a sternotomy. Complications included two (0.7%) strokes, two transient ischemic attacks, three (1.0%) myocardial infarctions, and seven (2.3%) reoperations for bleeding. The mean hospital stay was 5.2 ± 4.2 days. Sixteen (5.3%) patients required a mid-term or late reoperation. Mean postoperative echocardiographic follow-up studies at 2½ years demonstrated the following degrees of mitral regurgitation: none/trivial, 192 (68.8%); mild, 66 (23.6%); moderate, 15 (5.4%); and severe, 6 (2.2%). From these data, we concluded that robotic mitral valve repair was safe and associated with good mid-term durability.

LIMITATIONS/FUTURE DIRECTIONS

Despite rapid procedural advances, our early clinical experience with computer-enhanced mitral surgery has defined many of the technologic limitations. Force or haptic feedback is absent in these devices; however, new strain sensors may soon allow for more control of force applied to robotic end-effectors. Thus far, we have been able to overcome the limitations of “touchless” surgery by relying on “ocular tactility.” That is with a high degree of visual acuity and magnification we can sense when knots are tight, bands are approximated closely to tissues, and calcifications are present. Nevertheless, the addition of haptic feedback assuredly will provide more latitude with these devices.

We have examined both experimental and clinical learning curves that are associated with robotic mitral valve repairs. A retrospective review of the first 80 mitral valve repairs using the da Vinci™ system suggested that learning curves can be flattened for learners (unpublished data). To study these curves, the group of 80 patients was divided into eight equal groups of 10 chronologic cohorts. Valve resection, repair, suture placement, knot tying, total robotic, cross clamp, and bypass times were analyzed in the first five 10-patient cohorts. All showed significant reductions in times when we compared the first group with the most recent operations. As expected, we proved that intraoperative robotic mitral repair surgery times decreased as more procedures were performed. Interestingly, the learning curve was most evident during the first 20 operations but thereafter was incremental improved. Depending upon further refinements and development of adjunctive technologies, computer-enhanced cardiac surgery should evolve and promises to be beneficial for many more patients. Moreover, instrument arm sizes must be reduced and a greater variety of end-effector tips developed before, we will see the robotic era in mitral surgery roll out to become standard of care. Future surgical imaging and positioning systems may allow us to do these repairs using 1 cm ports and perhaps even inside the beating heart using echocardiographic guidance.

CONCLUSIONS

A renaissance in cardiac surgery has begun, and robotic technology is providing benefits to cardiac surgeons and their patients. To be sure, improved optics and instrumentation, progressively smaller incisions, and simulated three-dimensional vision, and enhanced surgeon hand-eye coordination will facilitate greater adoption of these surgical techniques. The placement of wrist-like articulation instrument ends moves the pivoting instrument tip actions to the plane of the mitral annulus. This improves dexterity in tight spaces and allows ambidextrous suture placement. Furthermore, as an educational tool, the robotic system may have an expander potential for use by residents and experienced surgeons alike. In the near future, surgical vision and training systems may be able to model most surgical procedures through immersive technology. Thus, a surgeon may be able to simulate, practice, and perform the operation based strictly on preoperative imaging data.

This new science is a trek and not a destination. In this era of outcome-based medicine, surgical scientists must continue to
evaluate intracardiac robotics and related technology critically. Despite initial enthusiasm, caution cannot be overemphasized. Surgeons must proceed carefully as indices become a safe and successful modality. Traditional valve operations still enjoy long-term success with ever-decreasing morbidity and mortality, which remain as our measure for comparison. Nevertheless, robot-assisted mitral valve surgery has developed to become a safe and successful modality.

**SUGGESTED READINGS**

INTRODUCTION

Ischemic mitral regurgitation (MR) is a mechanical complication of coronary artery disease. Most commonly, ischemic MR is due to chronic left ventricle remodeling following myocardial infarction. The resulting papillary muscle displacement leads to tethering of the mitral valve leaflets and varying degrees of annular dilatation (Fig. 44.1). This entity should be distinguished from coronary artery disease and concomitant MR due to other causes such as degenerative mitral valve disease. Naturally, the repair techniques and long-term outcomes following repair are very different depending upon the underlying etiology. Acute ischemic MR is rare and is secondary to papillary muscle rupture or chordal elongation.

Ischemic MR is common and associated with significant morbidity and mortality. MR is observed in approximately 10% of patients undergoing cardiac catheterization and may be associated with 40% mortality within the first year of diagnosis. The increasing prevalence of coronary artery disease has resulted in a rise in the number of patients with ischemic MR requiring surgery. Despite advances in medical and surgical management, longitudinal data have shown poor survival for patients with ischemic MR compared with patients who present with MR due to other causes. Nevertheless, new technologies and recent studies have provided new insights into this challenging surgical problem. In this chapter, we review ischemic MR with regard to its pathophysiology, clinical presentations, diagnosis, and management.

PATHOPHYSIOLOGIC TRIAD OF MITRAL REGURGITATION

MR is defined as the backward flow of blood in systole from the left ventricle into the left atrium via the mitral valve. Minimal lesions might cause MR by reducing mitral leaflet coaptation. Therefore, a careful interrogation (identification, localization, and magnitude) for mitral lesions is essential to determine the chances of successful valve repair and to proceed with a tailored therapeutic plan for each patient. Three decades ago, Carpentier described a systematic analytic approach to patients with MR known as the “pathophysiologic triad of mitral valve regurgitation.” The triad emphasizes the importance of distinguishing between the medical conditions causing MR (etiology), the resulting lesions, and finally how these lesions affect leaflet motion (dysfunction).

Patients with type I dysfunctions have normal leaflet motion, and MR is due to annular dilatation or leaflet perforation (Fig. 44.2A). There is increased leaflet motion in patients with type II dysfunction, with the free edge of at least one of the leaflets overriding the plane of the annulus during systole (Fig. 44.2B). Lesions responsible for type II dysfunction include chordal elongation, chordal rupture, and papillary muscle rupture. Type III dysfunction refers to restricted leaflet motion, with the free margin of one or both leaflets pulled below the plane of the annulus into the left ventricle, thereby reducing leaflet mobility and coaptation during systole and leading to MR. Patients with type IIIa dysfunction have restricted leaflet motion during both diastole and systole, as in the case with rheumatic valve disease. Type IIIb dysfunction is caused by restricted leaflet motion during systole, which occurs in the setting of left ventricular dysfunction and dilation; apical and posterolateral papillary muscle displacement causes this type of valve dysfunction (Fig. 44.2C).

Ischemic MR can result from type I, II, or IIIb dysfunction (Table 44.1). Isolated type I dysfunction with annular dilatation is uncommon but may occur in basal myocardial infarction. An associated type I lesion in the setting of a primary type IIIb lesion is a common finding in ischemic MR, but the amount of annular dilatation is often less than that seen in degenerative disease. Type II dysfunction after myocardial infarction results from papillary muscle rupture, which usually involves the postero medial papillary muscle or occurs when a fibrotic papillary muscle elongates and causes leaflet prolapse, particularly in the commissural area (this a rare lesion). In rare instances, an isolated chordal rupture can cause type II dysfunction. Carpentier’s type IIIb dysfunction is the most common and significant form of ischemic MR.

NATURAL HISTORY OF MITRAL REGURGITATION

Ischemic MR following myocardial infarction is associated with significant morbidity and mortality. Notably, more adverse events are observed with increasing MR severity. Data from the Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications study showed that in patients following ST elevation MI, the absence of MR was associated with an 1.4% 30-day mortality rate compared with 3.7% in patients with mild MR and 8.6% in patients with moderate-to-severe MR. Late survival is also worse with a reported 5-year total mortality and cardiac mortality of 62% and 50%, respectively, for patients with ischemic MR compared with 39% and 30%, respectively, for patients without ischemic MR. Beyond survival, ischemic MR is associated with more frequent hospitalization for congestive heart failure, with 30% of patients requiring hospital admission within 3 years of diagnosis.

TYPE IIIb ISCHEMIC MITRAL REGURGITATION

Pathophysiology

Normal mitral valve function involves a complex three-dimensional interaction
among the leaflets, annulus, subvalvular apparatus, and left ventricular wall. Several anatomic and pathophysiologic changes are associated with the pathogenesis of ischemic MR. They include ventricular changes (wall-motion abnormalities and/or dilation with increased sphericity), subvalvular changes (papillary muscle infarction, displacement, or tethering), and annular changes (distortion, dilation). The initial insult in chronic ischemic MR is due to remodeling of the left ventricle after myocardial ischemia or infarction. This remodeling converts the shape of the left ventricle from ellipsoidal to spherical, which leads to regional annular and subvalvular distortion and ultimately to poor leaflet coaptation. It appears that left ventricular sphericity is more important than the actual ventricular volume or ejection fraction in the progression of ischemic MR. The primary ventricular alteration leading to ischemic MR is papillary muscle displacement. The pattern of displacement is complex and cannot simply be described as apical tethering. The papillary muscle tips are displaced away from the midseptal (anterior) annulus, that is, posterolaterally, apically, and away from each other. The tethering distance has been shown to correlate with the severity of ischemic MR. Papillary muscle tethering leads to apical tenting of the leaflets (restriction of the motion of the free margins of the leaflets), which prevents them from rising to the plane of the annulus to coapt with one another (Fig. 44.3). Recent animal studies also suggest that the remodeling process accelerates as the degree of MR increases. Clinically, this tethering of the secondary chordae can be seen echocardiographically in the form of the “sea-gull” deformation of the body of the leaflet.

Annular dilation is a common associated finding in chronic ischemic type IIIB MR. However, the degree of dilation can vary and does not necessarily correlate with the degree of MR. Annular flattening of the saddle also occurs in ischemic MR. Laboratory data support the notion that annular dilation is not a fundamental component in the pathogenesis of ischemic MR. It has been demonstrated that mild degrees of annular dilation observed during acute occlusion of the left anterior

---

**Fig. 44.1.** Mechanism of functional mitral regurgitation. Normal mitral valve and subvalvular apparatus (left). Ischemic mitral valve with pronounced posterior restriction in P3 after an episode of ventricular ischemia (right). LV, left ventricle.

**Fig. 44.2.** Carpentier’s functional classification in ischemic mitral regurgitation. Type I has normal leaflet motion, and mitral regurgitation is on the basis of annular dilation, which may occur in the setting of basal infarction. Type II dysfunction implies excess leaflet motion with the free edge of the leaflet(s) traveling above the annular plane during systole, which may occur after myocardial infarction due to papillary muscle rupture (acute) or papillary elongation (chronic). Type IIIB is the most common form of ischemic mitral regurgitation and results from restricted leaflet motion during systole secondary to apical and lateral papillary muscle displacement.
Acute severe type IIIb ischemic MR often presents with symptoms of severe heart failure and/or low cardiac output. Although MR resolves over time in some patients, it will persist in others and lead to chronic postinfarction ischemic MR. In these patients, chronic ischemic MR will appear up to 6 weeks (median 7 days) after myocardial infarction as the left ventricle remodels. Risk factors for postinfarction ischemic MR include advanced age, female gender, prior acute myocardial infarction, large infarct size, recurrent ischemia, multivessel coronary artery disease, and congestive heart failure.

In patients with chronic ischemic MR, two clinical scenarios are commonly encountered. Patients may present with moderate-to-severe MR, symptoms of congestive heart failure, or worsening left ventricular function, and are referred primarily for mitral valve intervention. The preoperative coronary angiogram in these patients shows significant multivessel coronary artery disease, which may or may not have lead to symptoms. These patients often have clear evidence of prior myocardial infarction and at least moderate left ventricular dysfunction. Other patients present with symptomatic multivessel coronary artery disease and are referred for coronary artery bypass grafting (CABG) with a varying degree of MR on preoperative ventriculography or echocardiography. An acute coronary syndrome or chronic stable angina is often the dominant presenting symptom in these patients. In addition, they may present with symptoms of shortness of breath and/or congestive heart failure.

### Diagnosis

Patients often have changes on their electrocardiogram (ECG), and a prior myocardial infarction may be noted in >80% of patients with chronic ischemic MR. When ECG changes are noted, evidence of a prior inferior wall infarct is more common than an anterior or a lateral infarct. Most patients are in sinus rhythm; however, in patients with left atrial enlargement, p-wave abnormalities and atrial fibrillation may occur. Conduction abnormalities are uncommon in these patients. In the acute setting, the chest radiograph may show pulmonary edema. With disease progression, enlargement of the cardiac silhouette (left atrial enlargement, ventricular dilation) is a common finding. Cardiac catheterization will typically show multivessel disease and, likely, segmental wall motion abnormalities on ventriculography.

Two-dimensional echocardiography/Doppler is essential in determining the MR mechanism and severity, along with the function of the left ventricle. The severity of MR can be determined by semiquantitative measurements using jet geometry and area in multiple views. With restricted leaflet motion (type IIIb), the direction of the jet is often toward the restricted leaflet, or central if associated annular dilation is present. In this context, imaging has revealed two major patterns of leaflet tethering in the setting of ischemic MR: symmetric and asymmetric. Asymmetric tethering is defined by the displacement of the posteroomedial papillary muscle, causing posterior leaflet restriction and leading to an eccentric jet toward the posterior wall of the left atrium. As opposed to asymmetric tethering, symmetric tethering results from the displacement of both papillary muscles, and a central jet is typically observed. This symmetric pattern is the one observed in the setting of functional MR secondary to overlapping dilated cardiomyopathy (Fig. 44.4). The severity of MR is quantified via calculation of regurgitant volume (the difference between the

Descending or distal left circumflex in an animal model did not result in ischemic MR. The aforementioned changes in left ventricular geometry, papillary muscle position, and annular dimensions interact to result in poor leaflet coaptation during systole, which is the final common pathway for type IIIb ischemic MR.

### Clinical Presentation

Type IIIb ischemic MR can occur in an acute or chronic setting. *Acute postinfarction ischemic MR*, without papillary muscle rupture, can be documented in many patients by physical examination, ventriculography, or echocardiography. Moderate-to-severe MR is present in up to 13% of these patients. Acute severe type IIIb ischemic MR often presents with the sudden onset of shortness of breath and/or angina. In most patients, this incident is preceded by an acute myocardial infarction, which may be silent particularly in diabetic patients. A minority of patients will present with symptoms of acute severe type IIIb ischemic MR.
Section II: Adult Cardiac Surgery

**SURGICAL INDICATIONS**

**Severe Ischemic Mitral Regurgitation**

Current practice guidelines do not separate recommendations for surgery according to the etiology of MR, but rather the severity of MR and the degree of symptoms. Most patients with severe ischemic MR, however, have symptoms of congestive heart failure. Therefore, per current guidelines, patients with severe, symptomatic MR have a class I indication for mitral valve surgery if their left ventricular ejection fraction (LVEF) is >55 mm. Patients with severe symptomatic MR, LVEF <30% and/or an end-systolic left ventricle dimension is >55 mm have a class IIa indication for mitral valve surgery, provided that chordal preservation is likely.

**Mild-to-Moderate Ischemic Mitral Regurgitation**

In this clinical scenario, patients are referred for myocardial revascularization secondary to symptomatic/severe coronary artery disease. Mild-to-moderate type IIIb ischemic MR is often an incidental finding. Current evidence demonstrates that CABG alone does not completely correct ischemic MR. One of the early seminal studies describing ischemic MR found that 40% of patients with moderate MR who underwent CABG alone were left with moderate or severe (3 to 4+) residual ischemic MR, and an additional 50% of patients had persistent mild (2+) ischemic MR.

More recently, data from the Surgical Treatment for Ischemic Heart Failure Trial, which enrolled patients with a LVEF ≤35% and coronary artery disease amenable to CABG, confirmed that mitral valve surgery with CABG is associated with better survival compared with CABG alone (hazard ratio 0.41, 95% confidence interval 0.22 to 0.77). These data have been criticized as biased secondary to confounding by indication. As yet, no prospective randomized data are available, although several such studies are ongoing.

**SURGICAL MANAGEMENT**

**Perioperative Considerations**

Standard monitoring is used in patients undergoing combined mitral valve repair and CABG. Insertion of a Swan–Ganz catheter allows assessments of pulmonary pressures and cardiac output, which is particularly helpful in patients with left or right ventricular dysfunction, or pulmonary hypertension. TEE also allows further assessments of the mechanism of MR and LV function. Epiaortic scanning of the ascending aorta is also recommended to rule out the presence of atherosclerotic lesions before aortic cannulation.

**Surgical Approaches and Cardiopulmonary Bypass**

*MEDIAN STERNOTOMY* is the surgical approach of choice in patients undergoing combined mitral valve repair and CABG, as well as in the reoperative setting. A right *anterolateral thoracotomy* may be used in select patients referred for isolated ischemic MR with prior CABG and patent grafts. These patients are placed in a 30 degree left lateral decubitus position, and a 12 to 15 cm right anterolateral thoracotomy is performed through the fourth intercostal space. Because the right thoracotomy approach does not require extensive mediastinal dissection, it is also an alternative if dense mediastinal adhesions are suspected (e.g., previous mediastinitis). In general, a right thoracotomy is contraindicated in patients with severe chronic obstructive pulmonary disease, moderate-to-severe aortic insufficiency, or a history of previous right-sided chest surgery.

**Myocardial Protection**

Mitral valve surgery is performed on cardiopulmonary bypass with intermittent antegrade or combined antegrade and retrograde blood cardioplegic arrest. Further myocardial protection can be obtained with moderate systemic hypothermia and local hypothermia with topical ice. In reoperative mitral valve surgery, specifically through a right anterolateral thoracotomy, it may be difficult to cross-clamp the ascending aorta. Therefore, other types of myocardial protection could be considered.
management such as beating-heart or moderate to deep hypothermia and fibrillatory arrest should be considered, provided that the degree of aortic insufficiency is not more than mild.

**Exposure of the Mitral Valve**

After completion of coronary bypass grafting, careful exposure of the mitral valve is essential before valve analysis. Our preferred approach is the interatrial approach through Sondergaard’s groove. The interatrial groove is incised, and the two atria are dissected and divided up to the fossa ovalis. This dissection exposes the roof of the left atrium, which is incised close to the septum and, thus, mitral valve. A transseptal approach may be useful in selected patients with a small left atrium or prior aortic valve replacement.

**Mitra! Valve Repair**

Mitral valve repair is the procedure of choice for correction of type IIIb ischemic MR. The main goal of valve repair is to restore a large surface of coaptation by reducing the septolateral dimension of the valve with a downsized remodeling (complete, rigid, or semirigid ring) annuloplasty.

**Segmental Valve Analysis**

The valvular apparatus is examined systematically with a nerve hook to assess tissue pliability and identify leaflet restriction. The anterior paracommissural scallop of the posterior leaflet (P1) constitutes the reference point. Applying traction to the free edge of other valvular segments and comparing them with P1 determines the extent of leaflet restriction. Using two hooks, it is then possible to confirm leaflet restriction (type IIIb dysfunction) due to posterior papillary muscle displacement, most commonly affecting the P2 and P3 segments. The mitral annulus is examined to assess the severity of associated annular dilation, which is common and may be asymmetric in type IIIb ischemic MR.

**Undersized Remodeling Ring Annuloplasty for Type IIIb Ischemic Mitral Regurgitation**

Remodeling annuloplasty using an undersized ring is the technique of choice in type IIIb dysfunction (Fig. 44.5). Most commonly, 2-0 braided sutures are used to implant an annuloplasty ring. In general, sutures in the septal and lateral portions of the annulus should be placed using a backhand orientation, and sutures in the anterior and medial portions of the annulus are placed with a forehand orientation. The full curve of the needle should be used to encourage deep, wide placement of individual sutures along the annulus. Because of the potential increased tension in the setting of type IIIb dysfunction with associated annular dilation, it is preferable to place the sutures very close together along the annulus, and suture crossover may be warranted. The anterior commissure is usually the most difficult area to expose and is usually approached last after placement of sutures along the septal, medial, and lateral portions of the annulus to place tension on prior sutures to expose this area of the annulus. Once sutures are placed around the annulus, standard ring sizers are used to select an appropriate ring size. Placing gentle traction on marginal chords in the A-2 portion of the anterior leaflet with a hook allows the height and surface

---

**Fig. 44.5. Surgical approach to ischemic mitral regurgitation. Typical findings with leaflet restriction predominantly in the P2–P3 region (A). Sizing the annulus with a Carpentier–Edwards sizer is based primarily on the surface area and height of the anterior leaflet (B). One places 2-0 braided annular sutures into the mitral annulus, taking advantage of the full curve of the needle, with the angle directed toward the ventricle to ensure passage through the annulus. The sutures in the annulus at the position of the anterior commissure and trigone are placed last, taking advantage of previously placed sutures to expose this area (C). After placement of a full remodeling Carpentier–McCarthy–Adams IMR Etlogix ring, the surface of coaptation is restored (below the plane of the annulus) (D).**
Area of the anterior leaflet to be measured. An additional measurement to consider is the intercommissural distance. Because leaflet restriction in ischemic MR results in less leaflet tissue available for coaptation, it is necessary to downsize a complete remodeling ring such as the Carpentier–Edwards Physioring by one or two sizes or to use a true-sized Carpentier–McCarthy–Adams IMR Etlogix ring to ensure an adequate surface of coaptation following annuloplasty. The Etlogix ring combines the principles of undersizing with the specific asymmetric deformation observed in type IIIb ischemic MR. Compared with a symmetric Carpentier–Edwards Physioring, the Etlogix leads to increased leaflet coaptation due to the reduced anteroposterior (AP) dimension in patients with ischemic MR. This ring downsizes the D3 dimension by two sizes and the D2 dimension by one size compared with the Physioring. Systolic anterior motion will not occur despite aggressive downsizing, because the restricted posterior leaflet cannot displace the anterior leaflet into the outflow tract. After a ring is selected (typical size 24 to 28 mm), the interrupted annular sutures are passed through it, respecting the associated geometry of the annulus. The individual sutures are then tied, securing the ring to the annulus. Once the downsized remodeling annuloplasty is completed, a saline test is used to confirm the line of coaptation along the margin of the leaflets. Nearly the entire orifice is occupied by the anterior leaflet, allowing the entire restricted posterior leaflet to contribute to coaptation (Fig. 44.6).

De-airing Process
Careful de-airing at the end of the procedure is essential. Carbon dioxide insufflation is used in all patients to reduce intracardiac air. A small vent should be left across the mitral valve to facilitate de-airing after closure of the left atrium. When most of the air is expelled from the heart, the aortic cross-clamp is removed. Additional de-airing is performed during the reperfusion period. The aortic vent is maintained on suction until the patient is totally weaned from cardiopulmonary bypass and complete air removal is confirmed by TEE.

Recurrent Mitral Regurgitation Following Repair
Recurrent regurgitation following repair of ischemic MR is complex and may be related to the viability of the coronary territory grafted, type of annuloplasty used at surgery, as well as anatomic factors related to the degree of ventricular remodeling. Advancements in imaging technologies have provided insights into the failure of mitral valve repair. One study using single photon emission computed tomography has shown that moderate ischemic MR typically improves when CABG is performed in patients with at least 5/16 viable segments. In fact, global LVEF alone does not completely predict recurrent MR. The detection of regional wall motion abnormalities is critical; such as quantitative measures such as Doppler strain are now used to predict mitral valve tenting.

Remodeling annuloplasty (complete, rigid, or semirigid ring) is also strongly recommended in patients with ischemic MR since flexible annuloplasty systems or suture annuloplasty techniques have been associated with recurrent MR. Midterm results on 100 patients undergoing combined CABG/mitral annuloplasty using a Duran flexible ring in patients with ischemic MR included a 29% rate of recurrent MR >2+ at a mean follow-up of 36 months. The Cleveland Clinic also reported a 30% incidence of recurrent 3+ or 4+ MR 18 months following mitral valve repair with the flexible Cosgrove–Edwards annuloplasty band. These observed failures in mitral valve repair may be related to the asymmetric tethering of the mitral valve, which is more severe toward P2–P3 in patients with ischemic MR. This observation led to the development of the Carpentier–McCarthy–Adams IMR Etlogix ring developed by Edwards Life-sciences (Irvine, CA). Clinical studies have confirmed that the Etlogix reduces the mitral tethering area and tenting height with survival free from recurrent MR ≥2+ being 95% at 15 months and 89% at 25 months. Echocardiographic factors associated with repair failure include posterior leaflet angle more than 45 degrees, distal anterior leaflet angle more than 25 degrees, tenting height more than 10 mm, and tenting area more than 2.5 cm². The size of the left ventricle may also have prognostic importance, with an end-diastolic dimension >65 mm associated with poor reverse remodeling following CABG even in the presence of viable myocardium (Table 44.2).

FUNCTIONAL MITRAL STENOSIS

In a recent study, 24 patients with ischemic MR who underwent restrictive ring annuloplasty were subjected to dobutamine stress echocardiography and a 6-minute walk test. None of these patients had MR, but compared with control patients, those who underwent mitral repair had higher resting and stress peak mitral valve gradients. Six-minute walk distances were also shorter in patients who underwent restrictive ring annuloplasty. The long-term significance of functional mitral stenosis, however, remains unclear. Other authors have suggested that persistent pulmonary hypertension following mitral valve repair of ischemic MR is due to left ventricle dysfunction rather than persistent mitral valve gradients.

ADJUNCTIVE TECHNIQUES

It should be remembered that revascularization of all viable myocardial segments is recognized to reduce ischemic MR and should be considered an important “adjunct procedure.” Cutting of secondary chords has been shown to decrease recurrent ischemic MR, although long-term data supporting this approach are lacking. Others have described patch augmentation of the posterior leaflet in order to increase the coaptation surface. Ischemic MR has been treated with papillary muscle repositioning using a pledgeted suture attached to the annulus, or interven-tricular papillary transposition. Resection of secondary chordae, ventricular plication, and septolateral “cinching” have also been shown to be of benefit in preclinical models. In our own practice, in addition to downsized rigid ring annuloplasty, we tend to cut the posterior strut chord to the anterior leaflet if we see a “hockey stick” deformity and tethering of the body of the anterior leaflet, in addition to closure of all clefts and indentations in the posterior leaflet if severe leaflet tethering is present (Fig. 44.7). If a residual leak is still present, we will cut restricted marginal chords, and either attach the leaflet margin to an adjacent chord, or add a neochordae.

New technologies as adjuncts to traditional surgery have also been reported. The Randomized Evaluation of a Surgical Treatment for Off-Pump Repair of the Mitral Valve study suggests that the Coapsys device (Myocor, Inc., Maple Grove, MN) decreases left ventricle volumes and MR at 2 years while also improving survival. Five-year follow-up with the Acorn CorCap device (Acorn Cardiovascular, St. Paul, MN) suggests that addition of this device to mitral valve surgery results in a greater reduction in left ventricle volume compared with mitral valve surgery alone. Neither of these devices are currently approved for use in the United States.

MITRAL VALVE REPAIR VERSUS REPLACEMENT

The higher rates of recurrent MR following repair in patients with ischemic MR compared with other causes of MR have led some to consider valve replacement instead of repair. Although some have found no difference in late survival between treatment approaches, others have found a benefit with repair. A recent meta-analysis of nine studies conducted between 2004 and 2009 suggests that mitral valve repair is associated with better early and late survival compared with replacement in patients with ischemic MR.

RESULTS

Operative Mortality

Early outcomes following CABG and mitral valve surgery in patients with ischemic MR have improved over the last 20 years. Some series have reported no difference in early mortality between patients receiving valve repair compared with valve replacement, and...
whereas others have shown a difference of more than 10%. Overall, operative mortality of patients undergoing cardiac surgery with ischemic MR ranges between 2% and 18%. Recent data from the Society of Thoracic Surgeons demonstrate an early mortality of 7.4% for patients undergoing mitral valve repair and CABG compared with 11.6% for patients undergoing mitral valve replacement and CABG.

Late Outcomes
Late survival for patients with ischemic MR is worse compared with patients with MR due to other causes. Medium-term (3 to 5 years) survival ranges from 60% to 85% depending on the risk profile of the population studied. In patients with less than severe MR, mitral valve surgery concomitant to CABG is associated with better long-term survival.

TYPE II ISCHEMIC MITRAL REGURGITATION
A minority of patients may present with type II ischemic MR. Leaflet prolapse results from partial or complete rupture of one papillary muscle, papillary muscle elongation, or, more rarely, chordal rupture.

Pathophysiology
Papillary muscle rupture is an increasingly rare mechanical complication of myocardial infarction. Papillary muscle rupture can occur during the acute phase of myocardial infarction; however, most patients present within 2 to 7 days after the initial ischemic insult. The rupture typically involves the posteromedial papillary muscle (75% vs. 25% for anterolateral papillary muscle) due to its singular vascular supply (either the right coronary artery or the circumflex artery in right- or left-dominant systems, respectively). In contrast, the anterolateral papillary muscle is supplied by the left anterior descending and circumflex arteries. Complete papillary muscle rupture will result in bileaflet prolapse with severe MR. Partial rupture of one papillary muscle involving one or more heads remains the most common lesion in patients with type II ischemic MR. Myocardial infarction often involves a limited area of the myocardium, which may explain the relatively well-preserved left ventricular function in most patients. Chronic papillary muscle elongation with leaflet prolapse due to remote myocardial infarction is also rare, and results from fibrotic transformation of a papillary muscle after myocardial infarction.

Clinical Presentation and Diagnosis
Patients with papillary muscle rupture often present with sudden development of congestive heart failure and cardiogenic shock. It is important to note that the sudden appearance of a systolic murmur and hemodynamic compromise may result from acute severe ischemic MR secondary to papillary muscle rupture as well as from ventricular septal rupture.

Clinically, it may be difficult to distinguish between these two entities despite differences in the characteristics of murmurs (the systolic murmur associated with ventricular septal rupture is loud, prominent at the left sternal border, and associated with a thrill, whereas the systolic murmur of ischemic MR due to papillary muscle rupture is softer, intense at the apex, and without thrill). Extensive myocardial infarction with cardiogenic shock associated with varying degrees of ischemic MR without papillary muscle rupture (acute type IIIb) is also part of the differential diagnosis. Preoperative examinations including two-dimensional transthoracic echocardiography, TEE, and cardiac catheterization are crucial to making the accurate diagnosis of ischemic MR due to papillary muscle.

Medical and Surgical Treatment
The principal goal of preoperative medical management is hemodynamic stabilization. This is best achieved with the use of inotropic agents and prompts insertion of an intra-aortic balloon pump. However, this stabilization phase should not delay surgical intervention in the form of mitral valve repair/replacement and coronary revascularization.

Chordal-sparring mitral valve replacement is the procedure of choice in most patients. This technique preserves postoperative left ventricular function, contributing to improved long-term survival of these patients.

Mitral valve repair using classic Carpentier's techniques can be applied to patients with papillary muscle elongation. Papillary muscle shortening is best performed by resecting the appropriate length of papillary muscle and suturing the fibrous cuff supporting the chords to the papillary muscle. Four or five circumferential simple sutures without pledgets should be used for this fixation. If the elongation involves only one papillary muscle head resulting in the prolapse of one valve segment, more conventional techniques of repair such as leaflet resection combined with sliding plasty or annular plication can be performed safely. Papillary tip transposition, which involves sewing the fibrous tip of the elongated muscle to a papillary tip at the normal height, can also be considered.

Results for Type II Ischemic Mitral Regurgitation
Published series have reported an operative mortality as high as 19%, with 5-year survival approximately 50%. Given the rarity of type II ischemic MR, most studies have involved small numbers of patients and included both mitral repair and replacement. More contemporary studies suggest that a perioperative mortality of close to 0% may be possible.

SUMMARY
Ischemic MR is a progressive and dynamic disease with important clinical implications for patients who present either acutely or in the chronic setting after myocardial infarction. As our understanding of ischemic MR evolves, the technologies used to manage these patients will continue to be refined. Currently, mitral valve repair can be performed with favorable early and late results. Despite the wealth of retrospective data, no prospective randomized data are available describing outcomes following the surgical correction of ischemic MR. Undoubtedly, our understanding of this challenging disease will evolve as these data are available.

SUGGESTED READINGS
Buckley O, Di Carli M. Predicting benefit from revascularization in patients with ischemic heart

**EDITOR’S COMMENTS**

Dr. Adams and his colleagues have truly been experts in the surgical treatment of ischemic mitral regurgitation. They have done an outstanding job discussing the pathophysiology as well as appropriate surgical types of repair. The point that I would like to emphasize include proper definition of mechanisms as well as the annular downsizing approach. I totally agree with the authors that a semirigid ring is preferably used in this particular situation.

The difficult area is deciding between repair and replacement for these types of patients. The positive for repair include that there seems to be some survival disadvantage. The down side includes a higher recurrence rate than replacement. These issues I believe will be settled based on randomized trials including through the cardiothoracic surgical network. The data will be analyzed and hopefully we will be able to learn the best practice approach for this issue. My own bias is that those patients with severe tethering probably have the highest recurrence rate. If one is not going to do a procedure to deal with the tethering in addition to the treatment of annular dilatation, then these patients should be considered for chordal-sparing mitral valve replacement.
Percutaneous Mitral Valve Repair
D. Scott Lim and Gorav Ailawadi

INTRODUCTION
As the preceding decades have witnessed the maturity of surgical therapies for valve and coronary artery disease, the next decade will witness a tremendous change in our approach to percutaneous therapies for heart valve disease. Recently, we have seen a remarkably explosive growth of percutaneously implanted heart valves in Europe, and a myriad of novel devices being developed for repair or replacement of diseased heart valves from a transcatheter approach. This chapter will focus on novel percutaneous options for repair of mitral valve regurgitation.

HISTORICAL PERSPECTIVE ON PERCUTANEOUS THERAPIES FOR MITRAL VALVE DISEASE
The very first percutaneous therapy for mitral valve disease was the balloon mitral commissurotomy for rheumatic mitral stenosis. Since then, the technique has matured with the use of specific shaped balloons, and a better understanding of the types of rheumatic valve disease amenable to this therapy, as well as the long-term outcomes from this percutaneous approach. However, it is also important to note that the skills and techniques involved with this procedure are complex and involve a transseptal puncture, which is not commonly performed by most physicians trained today (Fig. 45.1).

Adapted from a Surgical Approach to Mitral Regurgitation
Currently, surgery for MR has become a mature therapy, with a wide range of different techniques involving leaflet, chordal, and annular approaches. Concepts behind each of these approaches have been utilized by novel transcatheter approaches to repair of MR. Additionally, work continues to create a transcatheter replacement option for mitral valve disease.

Indirect Annular Approaches to Mitral Regurgitation Therapy
The concept of a percutaneous annular approach mimics the surgical concepts of annular diameter reduction and bringing the posterior part of the annulus anteriorly, thereby pushing the posterior leaflet forward to create a better coaptation with the anterior leaflet. While later percutaneous devices have focused on direct approaches to the annulus, early designs have attempted to follow the course of the coronary sinus. However, they have been limited by the anatomic fact that the coronary sinus does not run in the same plane as the mitral annulus, as well as the incidence of circumflex artery crossing the coronary sinus.

The coronary sinus devices were introduced from a percutaneous, transjugular approach. One of the first such devices tested was the Edwards Lifesciences MONARC system—it was implanted in the coronary sinus with distal and proximal self-expanding stent anchors, and had a variable length connecting bridge. The connecting bridge had dissolvable polymers that would foreshorten over a period of weeks, changing the radius of curvature of the coronary sinus and bringing the posterior portion more anterior. It was studied in 72 patients—mainly with moderate degrees of MR, but with limited efficacy (able to be implanted in 82%, and a sustained reduction of mitral regurgitation by 1 grade in ~40%) and an incidence of complications of 28% at 2 years. Likely due to the inability to study the affects and risks of this device acutely, further study on this device was stopped.

Other coronary sinus devices such as Cardiac Dimensions’ Carillon device has had more success. It too is implanted with proximal and distal coronary sinus anchors, but with acutely observable affects on MR and is retrievable if needed due to inadequate efficacy or complication. It was studied in the European AMADEUS and TITAN trials in small numbers of patients also with mainly moderate degrees of functional MR. It was able to be implanted in ~66% of intended patients, and an ultimately low incidence of complications (~13% in the early AMADEUS trial and decreasing to ~2% in the later TITAN trial). Its efficacy was limited (~1 grade improvement in indices of MR) but promising in the appropriately selected patients. It has recently been awarded regulatory approval in Europe.

Similarly, Viacor’s PTMA coronary sinus device was studied in the PTOLEMY 1&2 trials, demonstrating in a small number of
While this technology has remained in approach is used for mitral balloon commissurotomy annulus repeatedly. The annulus directly, with catheters com­
ing at the annulus from both the left atrium and left ventricle. However, these therapies remain in early research stages. A poten­tially promising approach uses radio-frequency energy to cause scarring and contraction of the collagen in the annulus. While this technology has remained in relatively early preclinical trials, it holds promise in that no hardware is implanted and the therapy may be applied to the annulus repeatedly.

**Leaflet Approaches**

One approach, which ultimately matured into a catheter-based therapy, is the edge-to-edge approach as described by Alfieri’s group. In this surgical leaflet therapy, the central edges of the anterior and posterior leaflets are anastomosed creating a double-orifice mitral inflow. The concepts of this edge-to-edge approach were used by both the Edwards Lifescience’s Mobius device and Abbott Vascular’s MitraClip to create some of the first novel catheter-based therapies for MR. The Mobius device utilized a 17F delivery system from a percutaneous, transvenous, and transseptal approach. Its therapy catheter contained a vacuum port which was used to grab the leaflets, through which it would then throw a stitch, secured with a nitinol clip, mimicking the Alfieri edge-to-edge approach. This device was evaluated in the Milano II trial, which demonstrated limited efficacy both acutely and at 30 days, ultimately leading to its abandonment.

The MitraClip’s early design iterations attempted to duplicate this same suture-based approach to leaflet apposition, and involved using hollow needles to pierce the central portions of the anterior and poste­rior leaflets to deliver pledged sutures (Fig. 45.2). This technique worked on the open, nonbeating heart but it was soon realized that an independent mechanism to grasp the leaflets while they were in motion was needed to be incorporated into the design concept.

**MITRACLIP SYSTEM**

This novel percutaneous approach was the first achieving success in prehuman and clinical trials for treatment of patients with nonrheumatic MR. The concept of leaflet grasping by a clip mechanism on the regurgitant portions of the mitral valve became the hallmark of the final design freeze of the MitraClip (Fig. 45.3; Abbott Vascular, Santa Clara, CA). The MitraClip is introduced from a percutaneous, transvenous, and transseptal approach to the mitral valve (Fig. 45.4). The traditional imaging modality in the catheterization laboratory of fluoroscopy is of limited utility in this procedure, as it cannot visualize the mitral leaflets. Therefore, the procedure is guided by simultaneous transesophageal imaging, ideally using both two- and three-dimensional echocardiogra­phy (see Figs. 45.5 and 45.6). Combined with the reality that the MitraClip delivery system is manipulated by a mechanical-based device, it is more important that the valve interventionalist be skilled in transesopha­geal imaging than the standard catheter and wire skills.

By placing the MitraClip on the central portions of the anterior and posterior leaflets, it acts to anchor prolapsing or flail segments, as well as coapt tethered leaflets so that it reduces the time and force required to close the valve. By decreasing MR, the left ventricular volumes are in turn reduced, leading to beneficial left ventricular remodeling. Anatomically, the MitraClip creates a tissue bridge between the two leaflets, which limits dilation of the mitral annulus in the septal-lateral dimension, which supports the durability of this repair.

**EVEREST I AND II TRIALS**

This MitraClip approach to percutaneous mitral valve repair was evaluated in the EVEREST trials. EVEREST I was the safety and feasibility registry, which enrolled 55 patients in a nonrandomized clinical trial. EVEREST II was the pivotal clinical trial in which 279 patients with 3 or 4+ MR were randomized to either the Mitra­Clip therapy or standard surgical therapy (either mitral valve repair or replacement). It is important to note that this involved low­ and moderate-risk patients, in comparison to the EVEREST—High Risk Registry, which enrolled 79 patients who were nonoperative candidates to the MitraClip therapy. In the early nonrandomized experience with the MitraClip, procedural success (reduction of MR to 2+ or less) was achieved in 74%, and 66% were free from death, mitral valve surgery, or MR >2+ at 12 months. These outcomes were similar for those with either degenerative (79%) or functional (21%) etiology of MR. It is also important to note that this represents the initial experience with this novel technology, which has a steep learning curve.

The randomized EVEREST II trial included operative-candidate patients with either moderately severe or severe MR. Patients were either symptomatic, with a left ventricular ejection fraction (LVEF) >25% and left ventricular end­systolic dimension (LVESD) of ≤55 mm, or asymptomatic with ventricular dysfunction (defined as LVEF <25% to 60% or LVESD ≥40 mm), or pulmonary hypertension. Patients were excluded if they had need for other cardiac surgery, recent acute myocardial infarction (within 12 weeks), severe renal insufficiency (creatinine >2.5 mg/dl), endocarditis, or rheumatic etiology of valvar dysfunction. Additionally, patients were excluded for certain anatomical issues of the mitral valve—stenosis with mitral valve area <4.0 cm², a severely broad flail width (≥15 mm) and flail gap (≥10 mm), or deficient coaptation length (<2 mm).

Compared with patients from either the Society of Thoracic Surgery database or those undergoing first time elective mitral valve surgery, those enrolling in the EVEREST II trial were significantly older, with more comorbidities. This is likely due to the preference for the initial experience with novel percutaneous therapies to be reserved for patients who are less ideal surgical candidates. This randomized trial was designed to have a primary safety endpoint powered for a superiority hypothesis, for major adverse events at 30 days. The primary effectiveness
Fig. 45.2. Initial patent drawings of an early design iteration are shown in this device to create a percutaneous mitral valve repair. The idea behind this device is to use hollow needles to perforate the anterior and posterior mitral valve leaflets, and then throw pledged suture, mimicking the Alfieri-type repair. Unfortunately, this early design did not account for mobility of the leaflets in the real patient, and a separate grasping mechanism was required. SVC: superior vena cava; RA: right atrium; IAS: interatrial septum; TV: tricuspid valve; IVC: inferior vena cava; FO: foramen ovale; LA: left atrium; MV: mitral valve; LF: valve leaflet.

Fig. 45.3. A schematic view of the MitraClip is shown, which is used for percutaneous repair of mitral regurgitation. The blue arms are mechanically hinged and allow the operator to change the angle between them. These arms are designed to be pulled up from the ventricular side of the mitral leaflets to bring them together. The reddish spiked frictional elements may be lowered onto the atrial side of the leaflets, thereby sandwiching each leaflet between the blue arm and the red frictional element. Image provided courtesy of Abbott Vascular Structural Heart.

Fig. 45.4. Fluoroscopic image demonstrates the transvenous, transseptal approach to introduce the MitraClip to the mitral valve.
randomized to the MitraClip arm had a major adverse event rate of 15% at 30 days, versus those in the surgical arm had an event rate of 48% ($P_{\text{diff}} < 0.0001$). Further detailed analyses of the major adverse events such as death, stroke, re-operation, or emergent surgery demonstrated no such events occurring in patients receiving the MitraClip alone, but occurred in those crossing over to surgical therapy following unsuccessful MitraClip therapy. Therefore, in a per protocol analysis, which evaluates just the performance of the device alone rather than a strategy approach, the major adverse event rate was under 10% at 30 days.

From the primary effectiveness endpoint, in terms of the clinical composite of freedom from death, mitral valve surgery/reoperation, or MR $>2+$ at 12 months by an intention-to-treat analysis, the MitraClip arm had a success rate of 55% versus the surgical arm had a success rate of 73% ($P_{\text{diff}} < 0.0012$). Further analysis of the events driving the composite endpoint demonstrates that there was no significant difference between the MitraClip arm and the surgical control arm with respect to death or freedom from severe MR, but that the difference in composite endpoints was due to a difference in subsequent surgery for mitral valve dysfunction ($P < 0.001$). MR reduction to the goal and maintenance at 12 months of 2+ or less was achieved in 81% of the MitraClip patients, versus 97% of the surgical patients, although this was achieved by mitral valve replacement in 12% of surgical patients. Despite this difference in echocardiographic-measured MR reduction, there were similar reductions in left ventricular dimensions and volumes achieved at 12 months. Additionally and paradoxically, despite the differences in apparent MR reduction, there were a greater percentage of patients from the MitraClip arm who were asymptomatic or minimally symptomatic at 12 months (98%) versus those in the surgical arm (88%). Some of these apparent inconsistencies may be due to the difficulties in quantifying the degree of residual MR after a MitraClip has been placed in the center of the valve.

Quality-of-life indices, as measured by an SF-36 survey, demonstrated improved scores on both physical and mental evaluations in the MitraClip arm at 30 days, versus impaired physical and indeterminate mental scores at 30 days in the surgical arm. At 12 months, there were improvements in all study arms.

**EVEREST HIGH-RISK REGISTRY**

A separate U.S. registry was created for nonoperative patients with severe MR, from either degenerative (prolapse or flail) or functional etiologies (MR secondary to ischemic or nonischemic cardiomyopathy)—the EVEREST High Risk Registry. This registry enrolled 79 patients rapidly, as there was significant support for it from surgical colleagues. The majority of patients in the High Risk Registry had functional etiology of their MR, as would be expected from finding more patients with ischemic etiologies in a higher risk subgroup. Additionally, patients were older (average age 76 years with 68% over age 75) and more symptomatic (New York Heart Association functional class III or IV in 89%) than the randomized EVEREST population.

Data presented showed that while at 30 days the predicted mortality for the group was 18%, the actual mortality was under 8%, with 76% surviving at 1 year and 79% of the survivors in New York Heart Association symptom class I or II. In a nonrandomized comparison to similar high-risk patients treated medically, there was a survival advantage at a year, with 76% alive in the MitraClip group versus 55% in the medically treated group ($P = 0.037$). These data give support to the concept that particularly for these nonoperative patients, novel percutaneous options are attractive.

In Europe, along with the MitraClip having become a commercially available therapy, there is an ongoing...
nonrandomized registry collecting clinical and health economic data on treatment options for MR. Based on physician and patient choice, patients either receive MitraClip therapy, medical management, or standard surgical therapy. The patients undergoing MitraClip therapy continue to be older (41% of an age >75 years), with more comorbidities (49% cardiomyopathy, 45% with renal disease, and 19% with lung disease), and at high risk (average logistic EuroSCORE predicting mortality in 20%). Interestingly, unlike the U.S. experience, 87% had functional etiologic (either underlying ischemic or nonischemic cardiomyopathy causes of MR) and 41% had LVEFs between 10% and 30%. It is evident that the sweet spot for patient selection for this therapy is those patients that are not ideal operative candidates.

SUGGESTED READINGS
Dr. Scott Lim is a structural cardiologist and a very important colleague of mine. He happens to be a skilled technician and had outstanding results with percutaneous mitral valve repair. This type of technology sounds like it should clearly be a failure. However, I must say that it has been extremely useful in some very complex patients and it definitely has a role in the treatment of mitral valve regurgitation.

The advantages to the percutaneous approach are very little mortality or morbidity. The down side is that it is not a perfect repair. Most patients had some residual mitral regurgitation and certainly the technology does not deal with all the mechanisms of mitral regurgitation.

Having said all that, there are patients that clearly are at high risk for open mitral surgery. They are patients who could have been easily treated with this technology. Many of them do not need a perfect repair and clearly patients improve with this technology. The real difficulty is not to find patients that are inoperable but rather which patients who are operative but high risk but would be better suited to a percutaneous approach.

ILK
**INTRODUCTION**

The tricuspid valve is arguably the least understood valve in the heart. Most often, the tricuspid valve is affected in the setting of left heart disease, specifically with mitral valvular disease. In this scenario, the pathophysiology of tricuspid valve insufficiency is a result of elevated left heart filling pressures with subsequent development of pulmonary hypertension leading to right ventricular (RV) hypertrophy or dysfunction, and ultimately tricuspid annular enlargement. This is often termed “functional tricuspid regurgitation” as it is due to a failure of coaptation of structurally normal leaflets. Although tricuspid repair, in general, is a simple technique, according to the Society for Thoracic Surgeons (STS) National database, the operative mortality in patients undergoing tricuspid valve surgery with or without concomitant operation is roughly 10%. Moreover, data from individual centers report an operative mortality for reoperations for recurrent TR in excess of 30%.

As such, many surgeons have trepidation in treating patients with tricuspid valve disease. In fact, the need for surgical repair of tricuspid regurgitation (TR) is unclear and often debated by the surgical and cardiology community. First, the usually low-pressure, right-sided circulation is tolerant to imperfect function of the tricuspid valve. Second, tricuspid valve regurgitation most often occurs in the setting of left-sided pathology, resulting in a longer and more complex procedure with additive risk. The argument against addressing the tricuspid valve also stems from the improvement in tricuspid valve function often seen after correction of left-sided pathology. However, accurate predictors of tricuspid valve improvement after sole correction of left-sided pathology have not been convincingly or prospectively studied.

Isolated tricuspid disease is much less common, especially in adults. Patients typically present with right-sided failure symptoms. Patients with fixed pulmonary hypertension, severe RV dysfunction, and severe TR with no left-sided pathology are often the most challenging and have the greatest risk. The prognosis in this especially high-risk group of patients can be poor due to RV dysfunction, and operative intervention is often associated with dismal outcomes. Primary leaflet abnormalities of the tricuspid valve are less common and are caused most commonly by infectious endocarditis and carcinoid heart disease. Finally, Ebstein’s anomaly, although most commonly treated in childhood, may also be first diagnosed in adulthood in its less severe forms.

The ACC/AHA has provided guidelines for operative intervention for tricuspid disease. Class I indications for surgical intervention include (1) patients with severe TR undergoing left-sided surgery, (2) primary severe TR without severe RV dysfunction, and (3) severe primary or secondary tricuspid stenosis. Class IIa indications include patients with moderate TR in the setting of left-sided surgery with or without tricuspid annular dilation (>40 mm by echocardiography). It should be noted that all guidelines are based on level C evidence indicating that this field is largely guided based on retrospective series.

**EVALUATION AND OPERATIVE INDICATIONS**

**Functional Tricuspid Regurgitation**

Tricuspid annular dilation of the tricuspid valve due to left-sided pathology leads to functional TR. Generally, the annulus adjacent to the septal leaflet does not dilate, whereas the anterior and especially the posterior annulus dilates causing functional TR. Echocardiography is the most helpful modality in evaluating tricuspid valve regurgitation and distinguishes between annular problems and primary leaflet problems. Evidence of severe tricuspid insufficiency includes dilation of the right atrium, right ventricle, and inferior vena cava, along with a large color flow jet across the tricuspid valve. Hepatic vein flow reversal is likewise diagnostic. It is important to note that the degree of TR can be quite variable based on loading conditions and fluid status. Preoperative coronary artery catheterization is usually done given the typical patient age. Importantly, the assessment of right-sided hemodynamics should be done to evaluate RV function and pulmonary hypertension as these are significant predictors of outcomes in patients with TR. It should be noted that the degree of tricuspid regurgitation is poorly assessed by cardiac catheterization, while tricuspid stenosis can be diagnosed with this invasive test.

We often perform tricuspid annuloplasty in patients with more than moderate (>2+) TR in the setting of mitral valve disease. Selected patients with concomitant 2+ TR are also treated if there is any (1) evidence of RV dysfunction/significant pulmonary hypertension, (2) significant tricuspid annular dilation (annulus >40 mm), (3) elevated central venous pressure (>18 mmHg), or (4) in patients undergoing concomitant maze procedure as we believe even lesser degrees of TR may be contributing to AF.

In patients with isolated tricuspid insufficiency, surgical correction is warranted when symptoms are refractory to maximal medical therapy in selected patients. Often these patients will have difficult-to-treat right-sided congestive heart failure with significant peripheral edema and clinically significant passive congestion of the liver. Intensified diuretic administration often results in worsening renal function rather than improvement in the patient’s clinical status. Moreover, patients may...
develop signs of liver dysfunction from passive congestion. Tricuspid operation should be cautioned in patients with severe liver dysfunction (MELD > 15) due to high operative mortality.

**Endocarditis**

Infectious endocarditis involving the tricuspid valve is the most frequent valve involved in cases of endocarditis secondary to intravenous (IV) drug abuse. Endocarditis in these patients involves the tricuspid valve in three-fourths of these patients, whereas involvement of the mitral and aortic valve occurs in one-fourth of cases. Pulmonic valve involvement is much less common, accounting for <1% of cases. The other common groups of patients who develop tricuspid endocarditis are those who develop infections of indwelling pacemakers and leads. Transthoracic echocardiography is typically sufficient in screening and evaluating for tricuspid endocarditis. Transesophageal echocardiography can be performed in cases where the tricuspid valve is not seen well by surface echocardiography.

Surgical intervention for IV drug abusers with isolated right-sided endocarditis should be performed with caution. First, imperfect tricuspid valve function is overall well tolerated in these patients as the right side is a low-pressure system. Second, the consequences of embolization from the tricuspid valve to the lungs are less catastrophic than those from embolization from the left-sided valves. Most importantly, the risk of ongoing IV drug abuse with ongoing risks including reinfection and overdose also may necessitate a conservative approach to surgery in these patients. Two important indications for surgery for tricuspid valve endocarditis are (1) endocarditis caused by microorganisms that are difficult to eradicate such as fungal organisms or bacteria resistant to antibiotic therapy and (2) patients with tricuspid valve vegetations (>2 cm), a dilated right ventricle, and recurrent pulmonary emboli or right-sided heart failure. When surgery is necessary, debridement of infected tissue and preservation of the native valve is preferred when at all possible. Patients usually have significant degrees of valve regurgitation, and restoration of complete competence is neither possible nor necessary. Complete excision of the tricuspid valve will negate the risk of reinfection of an implanted prosthetic valve by continued IV drug use. This approach is not advocated by most surgeons since patients undergoing excision often have a challenging postoperative course and some eventually require prosthetic valve insertion secondary to poor cardiac output. Patients with pulmonary hypertension, sometimes related to multiple septic pulmonary emboli, will tolerate the absence of the tricuspid valve poorly.

In patients with infected pacemaker leads, the vegetation commonly involves the tricuspid valve. Diagnosis can be challenging in these patients as most patients with indwelling pacemaker leads have sterile vegetations on their leads without infection. Persistent positive blood cultures without other clear source or evidence of septic pulmonary emboli should prompt consideration for lead removal. While lead extraction alone may be sufficient therapy, in patients with large tricuspid valve vegetations (>2 cm) or significant TR, surgical removal and tricuspid repair should be considered. An alternative approach is the use of a hybrid approach with lead extraction by electrophysiologists and surgical tricuspid valve debridement and repair. Patients who require biventricular pacing may benefit from epicardial lead placement after tricuspid valve has been addressed and atrium closed. Great care must be taken to avoid cross-contamination of these new epicardial leads.

**Carcinoid Heart Disease**

Right-sided cardiac involvement is common in patients with carcinoid syndrome, although clinically significant lesions are much less frequent. Endocardial plaquing, the typical lesion seen in carcinoid heart disease, may involve either or both the pulmonary and tricuspid valves as well as the RV endocardial surface. Both tricuspid stenosis and regurgitation can occur in carcinoid disease. Evidence of tricuspid (and likely pulmonic) valve dysfunction and progressive right heart failure is the usual clinical presentation of patients considered for surgery. With current treatment of malignant carcinoid tumors, reasonable survival rates (>50% at 5 years) can be expected. Thus, patients with valvular dysfunction and progressive heart failure should be considered for valve replacement if their tumor is not imminently life-threatening.

**Ebstein’s Anomaly**

Ebstein’s anomaly causes varying degrees of TR and may be clinically silent or present at any time in children or adults. The lesion is characterized by downward displacement of the septal and often posterior leaflets of the valve into the right ventricle (Fig. 46.1). This gives the characteristic “atrialized” appearance of the right ventricle. The annular circumference is often quite large, and the right atrium is quite enlarged. The quality of the anterior leaflet is critical to the success of any attempted valve repair for Ebstein’s anomaly. The anterior leaflet is generally large, sail-like, and relatively thin. A thickened, muscularized anterior leaflet makes a poor substrate for repair. Ebstein’s anomaly valve may present along a spectrum of severity and may become clinically significant at any time during life and require surgical intervention.

Adults with less severe forms of Ebstein’s may become symptomatic and require surgical intervention. In adults presenting with Ebstein’s anomaly, symptoms may include arrhythmias, fatigability, dyspnea, and cyanosis. In addition, patients with Ebstein’s anomaly may have an associated atrial septal defect. Echocardiography is useful for characterizing the degree of valvular insufficiency and the quality of the leaflets, specifically the quality of the anterior leaflet when contemplating valve repair. Repair of the valve is obviously favored when possible. Replacement is necessary in some cases, however. In the neonatal period, transplantation or single-ventricle palliation (Starke’s procedure) may be required.

**Anatomy of the Tricuspid Valve**

The septal leaflet lies closest to the surgeon, the anterior leaflet away from the surgeon, and the posterior leaflet closest to the inferior vena caval cannula (Fig. 46.2). The anterior leaflet is quadrangular and is the largest of the three leaflets. Its chordae are derived from the anterior and posterior papillary muscles. The posterior leaflet generally is the smallest of the three leaflets and is triangular. Its chordae are also derived from the anterior and posterior papillary muscles. The septal leaflet is semicircular, with chordal insertion directly into the ventricular septum at its inlet and membranous portions. The membranous portion of the ventricular septum generally lies beneath the portion of the septal leaflet nearest to the anterosuperior commissure when looking in from the right atrium.

The atrioventricular node lies in the apex of the triangle of Koch, which is bounded by the septal annulus of the tricuspid valve, the coronary sinus, and the tendon of Todaro (Fig. 46.2). The bundle of His continues on from the atrioventricular node to pierce the central fibrous body that runs along the posteroinferior margin of the membranous septum. This close proximity of the atrioventricular node to the septal leaflet is of prime
的重要性对于三尖瓣手术非常关键。在三尖瓣瓣膜置换时，最安全的做法是保留部分间隔瓣组织，以便在放置瓣膜缝合线时避免损伤传导系统。大多数用于三尖瓣成形术的环都是为了避免将缝线放置在这一关键部位，而设计在环上留有空隙。

### Operative Setup

设置体外循环的三尖瓣手术，包括瓣膜成形术或合并主动脉瓣手术，取决于术者和麻醉师的偏好。由于主动脉瓣手术的需要，通常在体外循环后进行。在主动脉瓣手术前移除主动脉阻断钳，这增加了三尖瓣手术的难度，因为冠状窦和比目鱼窦中的血液会回流。

对于孤立的三尖瓣手术，我们可以使用低温。我们通常在不使用阻断的情况下进行这些手术，因为许多患者存在显著的右心室功能不全。在这种情况下，我们可以在一个标准的右房切口平行于房室沟，且远离它，以安全地关闭切口，不危及右冠状动脉。在切口制作后，可以通过悬挂切口边缘的丝线或使用支持系统来扩大视野。瓣膜叶和瓣膜下装置被仔细检查，瓣膜功能障碍的机制被确认并相应处理。

在右侧胸腔切口的三尖瓣手术中，右内颈静脉和股静脉插管是进行的。股动脉插管可以经股动脉直接进行，也可以在主动脉升部进行。标准的房切口是进行的。使用胸腔镜辅助的手术可以改善三尖瓣区的视野和照明。

TRICUSPID VALVE ANNULOPLASTY

Rigid Annuloplasty

Our standard approach for the functional TR is annuloplasty with a rigid or semi-rigid incomplete ring. The gap is in the area of the conduction system adjacent to the septal leaflet. There are little data on how to adequately size the tricuspid annulus. The septal leaflet is often used for reference as this part of the annulus usually does not dilate. Moreover, according to a report by Mohr and colleagues, the dehiscence rate is as high as 10% even in experienced centers.

We typically use 8-10 nonpledgeted 2-0 Ticron overlapping sutures. Larger travels are undertaken along the anterior and posterior annulus to create greater reduction annuloplasty in these areas. We often reinforce the first and last suture with an additional pledgeted 3-0 or 4-0 prolene suture as these are the areas at greatest risk for dehiscence (Fig. 46.4).

In those patients with extremely poor quality annular tissue, we use horizontal mattress sutures consisting of 2-0 Ticron with pledgets. Typically, there will be 3 to 4 mm space between each suture in the annulus and 1 mm of space between each suture as it is placed through the annuloplasty ring. This will ensure even distribution of the annular plication and tension around the circumference of the annuloplasty band.

De Vega

Long-term data with the De Vega technique have not been consistent. As such, we use the DeVega annuloplasty technique only rarely such as endocarditis where avoidance of any prosthetic material is preferred. A 3-0 Prolene double-arm pledgeted suture is used. The inner suture line is begun approximately 1 mm off of the tricuspid annulus and starts at the anterosepetal commissure. The bites are approximately 3 mm in depth and 5 mm in length, skipping 5 mm between bites. This inner suture line proceeds in a clockwise manner around the annulus to the posterospetal commissure. The outer suture line is 3 mm outside the first and is placed in a similar manner, in a clockwise direction to the posteroseptal commissure. A second pledget is passed onto the free ends of the suture. The suture is tightened down over a 28-mm tricuspid ring sizer or a 60 cm³ syringe.

Suture Bicuspidization

An additional technique popularization by Cohn and colleagues involves suture

Fig. 46.4. (A) Tricuspid valve annuloplasty. Placement of annuloplasty sutures in horizontal mattress manner with needles passed through the annulus. (B) Completed tricuspid valve annuloplasty using Carpentier-Edwards ring.
bicuspization of the tricuspid valve. With this technique, a pledged 2-0 Ethibond or Ticron suture on a large needle is run from the anteroposterior to the posteroseptal commissure along the posterior annulus. The second suture is passed in a similar manner and an additional free pledget is placed (Fig. 46.5). The suture is tied down with a dilator (similar to the DeVega technique). The net result is exclusion of the posterior leaflet and a functional bicuspid tricuspid valve.

**Other Techniques**

Other methods that are established and proven for the mitral valve including leaflet resection, Alfieri plication, and artificial cord placement can also be applied in rare cases of prolapse of the tricuspid valve or in cases of endocarditis.

**TRICUSPID VALVE REPLACEMENT**

Tricuspid valve replacement may be indicated for infectious endocarditis, failed previous tricuspid repair, failing previously placed valve prosthesis, or the more rare instances of carcinoid heart disease or rheumatic disease. Prosthetic replacement of the tricuspid valve with either a bioprosthetic or mechanical valve has been generally shown to be equally safe, although most would place a bioprosthetic valve in patients with concern for compliance with anticoagulation.

The setup for tricuspid valve replacement is similar to that for a tricuspid valve repair. We tend to debride only the diseased portions of the tricuspid valve and preserve as much chordal apparatus as feasible similar to chordal-sparing mitral valve replacement (Fig. 46.7A). If the septal leaflet requires excision, leaving a 2-mm margin of septal leaflet adjacent to the annulus for suture placement may help to avoid injury to the conduction system. Whether a bioprosthetic or mechanical valve is chosen, 2-0 Ticron-pledged horizontal mattress sutures are

**Fig. 46.6.** (A) Tricuspid valve excision leaving a 2-mm margin of septal leaflet tissue adjacent to the annulus. (B) Suture placement for tricuspid valve replacement. (C) Completed tricuspid valve replacement.

**Fig. 46.7.** Danielson repair. (A) Pledged horizontal mattress sutures draw the tricuspid leaflets up to the tricuspid annulus. (B) Posterior annuloplasty suture lessens the annular circumference, creating a functional monocuspid valve based on the anterior leaflet.
placed with the needles entering just outside the tricuspid valve annulus and exiting from within the tricuspid annulus from atrium to ventricle and through the leaflet (Fig. 46.7B). In the area of the septal leaflet, the sutures are passed through the remnant of the leaflet to avoid injuring the conduction system. The valve sutures are then passed through the sewing ring, the valve is lowered into position, and the sutures are tied and cut (Fig. 46.7C). In the case of placement of a bioprosthetic valve, the orientation of the valve is not critical because RV outflow tract obstruction by one of the struts is unlikely.

**TECHNIQUE OF VALVE REPAIR FOR EBSTEIN’S ANOMALY**

For repair of Ebstein’s anomaly, the usual preparation is made for cardiopulmonary bypass. Bicavalvenous cannulation is used. Usually, the right atrium is enlarged and cannulation of the superior vena cava via the right atrial appendage is used. Mild hypothermia is used. The aorta is cross-clamped and antegrade cardioplegia is delivered. Once adequate myocardial preservation has been attained, a generous right atriotomy is made keeping in mind that in cases of a markedly enlarged right atrium an ellipse of right atrial wall may be removed. The tricuspid valve and atrial septum are evaluated, and if an atrial defect is present, it is closed after the tricuspid has been repaired. A cardiomyectomy or vent catheter can be placed through the atrial septal defect during the tricuspid repair to facilitate visualization. The leaflets of the tricuspid valve are evaluated with particular attention to the morphology and quality of the anterior leaflet. Less satisfactory results can be predicted by the presence of a thickened muscularized anterior leaflet with fused or indistinct chordae. The Danielson and Carpentier methods of repair have both been used successfully; however, we have found the Carpentier repair to provide excellent results, given the appropriate candidate valve.

The Danielson repair (Fig. 46.8) in the adult involves the vertical plication of the atrialized portion of the right ventricle and creation of a functional monocuspid valve based on the anterior leaflet. A portion of the right atrium is also removed to normalize its size. Pledged horizontal mattress 3-0 Prolene sutures are placed from the downwardly displaced tricuspid valve to the tricuspid annulus. These sutures are tied down, drawing the tricuspid valve up to the tricuspid annulus and thus excluding the atrialized portion of the right ventricle. A 3-0 Prolene mattress posterior annuloplasty suture is also placed to reduce the annular circumference. Additional sutures may be placed to obliterate the remainder of the posterior tricuspid annulus. The atrial septal defect, if present, is closed.

The Carpentier repair uses longitudinal plication of the right ventricle and tricuspid annulus with resultant reduction in annular circumference. The anterior leaflet is detached along most of its annular circumference, and a sliding plasty is performed following annular plication using 4-0 Prolene running suture. This redistributes the anterior leaflet

**Fig. 46.8.** Carpentier repair. (A) Anterior leaflet is detached from the tricuspid annulus. (B) Vertical plication of tricuspid annulus. (C) Redistribution and reattachment of the anterior leaflet to the remodeled tricuspid annulus. (D) Finished repair is supported by an annuloplasty ring.
around much of the refashioned annulus. The result is effectively a monocuspid valve that spans the tricuspid orifice. The repair is supported by the placement of a Carpentier annuloplasty ring using the method described previously in this chapter. Given an adequate annular reduction and an anterior leaflet of reasonable quality, a dramatic reduction in TR can be expected.

**SUGGESTED READINGS**

---

**EDITOR’S COMMENTS**

The surgical treatment of the tricuspid valve may be one of the more controversial areas in cardiac surgery. There are multiple decent techniques for repair but unfortunately all have their issues. I believe presently there are enough good studies that if one truly has to do a repair for an isolated tricuspid valve disease, a ring repair is probably the best approach. Other suture approaches may be appropriate in patients who require the tricuspid valve fixed at the time of mitral valve surgery.

Surprisingly, though this is an operation on the right side of the heart, tricuspid valve surgery carries a significant mortality. Most frequently, this occurs due to comorbidities particularly congestion of the liver, which does not get better immediately. I think it is clear now that tricuspid repair should be done in patients who have rightsided congestion when done as an isolated procedure. Repair should be done in conjunction with left-sided valve procedures when there is moderate or severe tricuspid regurgitation or in some case when the annulus is markedly dilated.

ILK
PULMONARY VALVE REPLACEMENT AND TETRALOGY OF FALLOT

Dysfunction of the right ventricular outflow tract (RVOT), whether is due to stenosis or regurgitation, is a common and challenging condition in both children and adults with congenital heart defects. Some of these defects include pulmonary atresia, d-transposition of the great arteries with pulmonary stenosis, truncus arteriosus, double outlet right ventricle, and most commonly tetralogy of Fallot (TOF). Pulmonary valve replacement (PVR) remains the gold-standard of care for the definitive surgical treatment of progressive right ventricular (RV) failure from these defects due to longstanding pulmonary regurgitation (PR) and pulmonary stenosis. Often occurring two to three decades after surgical repair of TOF, PR has become an increasingly more common clinical situation confronting congenital and adult cardiac surgeons as outcomes and survival have improved for TOF patients over the past several decades. TOF still remains the most common type of cyanotic congenital heart defect. Surgical palliation of TOF was first popularized with the introduction of the Blalock-Taussig systemic-to-pulmonary artery shunt in 1945, and surgical management of this condition for a majority of patients has evolved over the past 50 years to include primary repair of each associated defect during infancy. With advances in surgical technique, diagnostic imaging and technology, postoperative and critical care management, and long-term follow-up capabilities, outcomes following primary TOF repair have dramatically improved with current mortality rates of 2% to 3% and 20-year survival approaching 90%. Despite these successes, significant anatomic and functional abnormalities remain following surgical treatment of TOF that confer important long-term cardiopulmonary implications.

The recognition of certain adverse functional sequelae following TOF repair has been increasingly reported and emphasized in recent years. These abnormalities include RV failure from progressive volume overload and PR, persistence of atrial and/or septal defects, RV outflow obstruction, pulmonary artery stenosis, and tricuspid regurgitation. While these lesions are often benign during childhood and adolescence, they have the potential to progress and significantly compromise patient functional status, exercise tolerance, and survival by the second or third postoperative decade. Moreover, severe, progressive chronic PR is considered a treatable cause of RV failure and has been the focus of increased study and investigation in recent years.

This chapter reviews the general principles that apply to the pathophysiology of pulmonary valve dysfunction, indications and timing for treatment of severe and clinically significant pulmonary valve lesions, selection and availability of pulmonary valve prostheses, surgical technique of PVR, and recently reported outcomes for PVR.

PATHOPHYSIOLOGY OF PULMONARY VALVE DYSFUNCTION

The pathophysiology of pulmonary valve dysfunction following TOF repair is multifactorial, and the severity of pulmonary valve dysfunction has been shown to increase over time. While for many years, the impact of PR after surgical correction of TOF was considered relatively benign, evidence has demonstrated that progressive PV dysfunction results in right heart failure. Four primary factors influence the degree of PR following TOF repair: (1) regurgitant orifice size, (2) length of diastole, (3) diastolic PA to RV pressure gradient, and (4) pulmonary artery resistance and capacitance. Early after TOF repair, the effect of pulmonary valve regurgitation is minimal due to an increased heart rate and shortened diastole, decreased RV compliance due to RV hypertrophy, and decreased pulmonary artery capacitance. However, over time, physiologic changes occur, including an increase in RV compliance and stroke volume, increased PA compliance, and slowing of heart rate with a lengthening of diastole. These changes, therefore, predispose to the eventual development of worsening PR. Moreover, the progressive development of PR results in a cyclical pattern of worsening PV and cardiac dysfunction. Increased PR results in RV dilation and increased RV compliance that serves to increase RV stroke volume, ultimately resulting in elevated PA pulse pressures, increased PA dilation, and worsening of PR.

The development of improved cardiac imaging modalities has demonstrated important changes to RV mechanics following primary TOF repair that play an important role in the progressive decline in pulmonary valve function. In fact, a close relationship between RV end-diastolic volume and percent PR exists. While the effects of RV systolic function are preserved for several years despite significant PR, eventually compensatory mechanisms fail. Failure of RV compensation results in decreased RV mass-to-volume ratios, increased end-systolic volume, and ultimately decreased RV ejection fraction. In addition, PV function is further degraded due to the effects of age of repair; RV dyskinesia due to ischemia, fibrosis, RV aneurysm, or RVOT patch; impaired RV diastolic function; and increased LV size and dysfunction.

INDICATIONS AND TIMING OF PULMONARY VALVE REPLACEMENT

PVR has documented beneficial effects for PV dysfunction including improved ventricular function, reduced atrial and ventricular arrhythmias, and improved cardiac functional status. These benefits notwithstanding the clinical decision as to the timing of PVR and the identification of
clinical indicators for surgical valve replacement often remain a dilemma. Several clinical and physiologic indications exist for PVR following TOF repair. Clear clinical indication for PVR include symptomatic physical deterioration, decreased exercise tolerance, onset of clinical arrhythmia, clinical signs and symptoms of right heart failure as a result of severe PR, need for cardiac medications, and onset of syncope. However, indications for PVR in the asymptomatic patient are much less defined. In an era of advancing technology, several different cardiac functional metrics have been identified to aid in the decision to proceed with PVR. In the presence of moderate-to-severe PR, PVR is indicated in the presence of the following homodynamic factors as reported by Geva:

- RV end-diastolic volume index ≥ 160 ml/m².
- RV end-systolic volume index ≥ 70 ml/m².
- LV end-diastolic volume index ≤ 65 ml/m².
- RV ejection fraction ≤ 45%.
- Presence of RVOT aneurysm.

Other important factors include the presence of other hemodynamically significant lesions including moderate-to-severe tricuspid valve regurgitation or the presence of atrial and/or ventricular septal defects, TOF, or other congenital pulmonary outflow tract reconstruction after the age of 3 years. Moreover, an MRI-based study by Therrien and colleagues demonstrated that the optimal timing for PVR in adults following TOF repair occurred when RV end-diastolic dimension was <170 ml/m. When dealing with pulmonary stenosis, surgical indications include a RV pressure two-third of systemic regardless of symptoms.

### Selection of Available Pulmonary Valve Prostheses

Reconstruction of the RVOT remains a common surgical procedure in congenital heart surgery. There are several congenital heart defects that require this operation to prevent or reverse RV dysfunction that can result from long-standing pulmonary insufficiency or stenosis. Despite the high frequency of this operation, controversy still exists regarding the best valve replacement in the pulmonary position.

#### Pericardial Valve

There have been encouraging results with the use of the bovine pericardial valve. It has been associated with low morbidity and no perioperative mortality. Shinkawa et al. showed a freedom from reoperation of 97.7% at 5 years. At midterm follow-up, the mean pulmonary valve gradient was 19 mmHg, and 9% of the patients had freedom from more than moderate pulmonary insufficiency. Other studies supported these encouraging results. Allen et al. reported excellent early outcomes using bovine pericardial valves with 100% freedom reoperation at 5 years. Fiore et al. also showed promising early outcomes with 92% freedom from reoperation at 5 years. In that study, late valve dysfunction was lower in the bovine pericardial valve when compared with porcine valves and homografts (5.5% vs. 19% vs. 54%, respectively).

There are several theoretical advantages of pericardial pulmonary valves. The valve may deteriorate by both stenosis and regurgitation rather than regurgitation alone. Slow progressing stenosis may be less damaging to the right ventricle as compared with insufficiency alone, which can result in recurring RV dilation. Clearly, more studies specifically evaluating long-term performance and structural changes of these valves in the pulmonary position need to be completed to support this theory.

#### Mechanical Pulmonary Valves

The overwhelming experience of mechanical prostheses has been in the aortic position. The benefits of these valves include excellent long-term durability and potential freedom from reoperation. Obviously, the requirement of anticoagulation is a concern and carries its own set of risks. For patients, particularly adults, with congenital heart defects involving the pulmonary valve, this seems like a viable option in certain circumstances. Unfortunately, there exists only a small body of literature evaluating the use of mechanical valves in the pulmonary position. There have been conflicting reports with the use of mechanical valves in the pulmonary position particularly with respect to the use of a bileaflet versus monodisc valve (bileaflet valves had a higher rate of thrombotic complications). The range of thrombotic complications for mechanical valve in the pulmonary position, being a lower pressure system, is from 25% to 80%. However, the majority of patients studied in the past were only anticoagulated with aspirin. Stulak et al. showed excellent durability of mechanical pulmonary valves with freedom from reoperation at 5 years of 100% (vs. 90% for bioprosthesis) and at 10 years of 100% (vs. 52% for bioprosthesis). Furthermore, the average gradient was 13 mmHg across the valve in follow-up. There were no thromboembolic events when patients were adequately anticoagulated with warfarin. In addition, there were no reoperations for pannus formation, paravalvular leak, endocarditis, valve thrombosis, or prosthetic dysfunction with long-term follow-up. Although bleeding with anticoagulation remains a concern and is often a deterrent to use of mechanical valve prostheses, particularly in children, there are several advances that may decrease the future risk of anticoagulant-related bleeding. Contrary to historic data, achieving a slightly lower target INR may be beneficial. Further, there are new antiplatelet agents and direct thrombin inhibitors that have a wider therapeutic window and fixed dose. The side-effect profile is much less as compared with warfarin. In addition, INR self-testing has demonstrated decreased risk in bleeding complications from 10.9% to 4.5% and decreased risk of thromboembolism.

Given the excellent durability and hemodynamic profile combined with the low rate of thrombotic events (when adequately anticoagulated), mechanical PVR is a potentially viable alternative in highly selected circumstances (multiple prior operations, those requiring anticoagulation for something else, or patients who have demonstrated early or accelerated deterioration of previously placed tissue valves).

#### Pulmonary Homografts

Pulmonary homografts have been a commonly used conduit to reestablish RV to pulmonary artery continuity in a variety of congenital heart defects. Initial use of these conduits, with early preservation techniques employing antibiotics or irradiation sterilization, was associated with early failure. Over the years, the development of cryopreservation techniques have improved both the availability and durability of allografts, which has resulted in increased use of RVOT reconstruction. The freedom from reoperation rates reported for series of cryopreserved in the pulmonary position in the young have been 55% to 80% at 4 to 6 years. Some of the early failure rates of the pulmonary homograft may be related to age of the patient. Hawkins et al. described an increased risk of valvular degeneration in infants when compared with older children. In their study, children older than 1 year of age experienced a freedom from valve explantation or death of
94% at 3 years after surgery compared with 50% in children younger than 1 year of age. This has subsequently been supported by Brown et al. showing an almost double incidence of dysfunction and failure at 5 years in infants younger than 1 year of age.

Standard allografts are widely used at many centers for several reasons. They have excellent handling properties, are easy to insert, and have an acceptable hemodynamic profile after implantation. Pulmonary homografts have been preferred over aortic homografts in the pulmonary position because they have less elastic tissue and lower rates of calcification. One main issue with the homograft conduit is its variable durability especially in young children, which frequently require repeat operations. It is theorized that homograft failure is partially a result of host immune response to antigens present in the homograft. Specific cellular and humoral responses by the recipient contribute to early graft deterioration and tissue calcification with subsequent clinical failure. Infants and children tend to have the greatest immunologic reaction to cryopreserved homograft material with a shorter period of freedom from reintervention after implantation than seen in adults.

Decellularized cryopreserved valved homografts were developed to ameliorate the recipient immune response to implanted conduits. These homografts were also designed to provide an acellular matrix that could be infiltrated by autologous cells. In theory, a decellularized cryopreserved homograft repopulated with recipient cells would be capable of repair and remodeling similar to native tissue giving it increased durability. Despite evidence that these homografts do not elicit a significant immune response, and even though autologous cells have been shown to infiltrate decellularized autografts, there has been no definitive data demonstrating a clinical advantage over standard homografts. Unfortunately, most studies have been limited by small patient sizes as well as short duration of follow-up.

Burch et al. studied long-term follow-up of 47 patients undergoing RV to pulmonary artery conduit replacement using decellularized cryopreserved homografts and compared them with 47 age-matched and diagnosis-matched controls receiving standard homografts. There was a nonsignificant trend toward lower peak valve gradient and reintervention in the decellularized cryopreserved homografts. Several other studies have evaluated the performance of decellularized homografts in the RVOT position as compared with standard homografts. There have been no statistical differences between the two types of homografts with regard to reintervention in any study of short- or long-term function. Furthermore, decellularized cryopreserved homografts cost an average of $3,000 more than standard homografts. In addition, the shelf-life of these decellularized grafts is approximately one-tenth that of traditional cryopreserved homografts. There is, however, a particular patient population that might benefit from these decellularized grafts. Patients who progress to transplant may be a better choice for this homograft as they result in minimal activation of recipient immune system, thus preventing sensitization that would limit donor compatibility. It should be kept in mind that patients with congenital heart disease requiring RVOT reconstruction currently represent 15% of patients who ultimately progress to transplant.

**Percutaneous Pulmonary Valve Replacement**

The number of patients requiring RVOT intervention continues to grow. For patients who receive their first PVR at an early age, the number of operations becomes substantial. Percutaneous PVR, as first described by Bonhoeffer in 2000, has made remarkable progress over the years. The Melody transcatheter valve was FDA approved in 2010 for use in pediatric and adult patients who have failed RVOT conduits (stenotic or regurgitant).

Transcatheter PVRs are less invasive, avoid the risks associated with cardiopulmonary bypass, avoid risks of bleeding and infections, and potentially reduce the costs by avoiding postoperative intensive care. The valve that is a bovine internal jugular vein valve mounted in an expandable platinum iridium stent can be delivered percutaneously via the femoral or internal jugular veins. In addition, the valve can be delivered with a hybrid approach directly through the right ventricle without having to go on cardiopulmonary bypass. Percutaneous pulmonary valve implantation is currently approved to be performed in a >16 mm conduit with either a mean gradient of 35 mmHg or at least moderate pulmonary valve insufficiency and is expandable to 22 mm.

Several studies have shown a high rate of procedural success and encouraging short-term function of the percutaneous Melody valve. This could reduce the number of operations and the cumulative hemodynamic burden on the right ventricle over the total lifetime of children and young adults. This may in turn potentially improve the life expectancy of patients with congenital heart disease involving the RVOT. While initial trials have shown promising early results in certain subset of patients, long-term outcomes are currently lacking and complication rates in addition to reintervention rates are being closely evaluated.

**SURGICAL TECHNIQUE**

Reconstruction of the RVOT is a common surgical procedure in congenital heart disease. Preoperatively, a cardiac catheterization or magnetic resonance imaging scan is performed. Duplex studies may also be considered to evaluate the groin vessels for possible groin cannulation. All patients have an intraoperative transesophageal echocardiography performed to assess function and particularly any residual atrial or ventricular communications. The overwhelming majority of these surgeries are performed in the redo sternotomy setting. Once the chest has been opened and the mediastinal structures are dissected out, we typically place a single aortic cannula in the distal ascending aorta and a two-staged venous cannula in the right atrium. The patient is placed on cardiopulmonary bypass. The conduit replacement can be performed on-pump, with a beating heart and no cardiopulmonary arrest assuming there is no atrial or ventricular communication. If there is, then bivacaval venous cannulas should be placed and the heart should be arrested to repair the residual communications. Once completed, the aortic cross-clamp can be removed and the conduit replaced with a beating heart. Once on pump, the main pulmonary artery is transected at the distal confluence. The distal confluence and proximal branch pulmonary arteries are completely dissected out and freely mobilized for an easy distal anastomosis. The transannular patch is completely resected back to healthy RV tissue. Similarly, a previously placed conduit is also completely excised. The distal anastomosis is typically performed first between the distal conduit and the confluence of the pulmonary artery. Once completed, the proximal conduit can be trimmed accordingly and sewn to healthy RV muscle wall. A homograft can be inserted in a similar manner although some would prefer to perform the proximal anastomosis first and then trim the distal conduit before sewing the anastomosis to the pulmonary arteries. The entire operation can be performed no lower than moderate hypothermia (34°C).
OUTCOMES following performance of PVR are encouraging. Operative mortality remains low with most series reporting rates of <1%. Perhaps more importantly, long-term survival remains high with 5- and 10-year survival rates of approximately 90% to 92% and 75% to 85%, respectively. Freedom from reoperation and valve failure rates approach 80% at 5 years, 60% at 10 years, and 40% at 15 years. Young age at the time of PVR remains a well-established risk factor for reoperation and valve failure.

CONCLUSIONS

PVR following TOF repair remains the gold-standard treatment for RV dysfunction. With improved surgical outcomes and advances in modern postoperative care, the number of patients requiring PVR is likely to increase in coming years. Several different choices in valve prostheses are available to the surgeon, and advances in the percutaneous, transcatheter delivery of pulmonary valves may offer an attractive alternative for select patient populations. While outcomes following surgical PVR remain excellent, future comparative effectiveness study will help to determine the future place of percutaneous technology in the treatment of clinically significant PR.

SUGGESTED READINGS

The surgical treatment of the pulmonary valve has been one of the least understood chapters in adult cardiac surgery. Many of these patients have had previous repair of tetralogy of Fallot. Previously, surgeons tended to cut out all pulmonary valve tissue to prevent obstruction. We now know that this results in late right ventricular dysfunction due to pulmonary insufficiency.

The conduits for pulmonary valve replacement have changed over time as well. I use to favor homografts but with time even pulmonary homografts tend to have earlier dysfunction than expected. The use of valve conduits with tissue valves seems to be the best approach at this point with low mortality and certainly the ability to best preserve a damaged right ventricle. There is another huge advantage to the use of pulmonary valve conduits. It becomes a resting place for percutaneous pulmonary valves that are truly excellent technology. We use these at our institution and they work extremely well inside a degenerated conduit.
THE SURGICAL ANATOMY OF THE AORTIC VALVE

The normal aortic valve is composed of three thin, pliable leaflets or cusps attached to the heart at the junction of the aorta and the left ventricle. The leaflets are attached within the three sinuses of Valsalva to the proximal aorta and joined together in three commissures that create the shape of a corone. Because the coronary arteries arise from two of the three sinuses of Valsalva, the aortic leaflets are named after their respective sinuses as the left coronary leaflet, the right coronary leaflet, and the noncoronary leaflet. However, because of the oblique position of the aortic root, the sinuses themselves are rarely in a strict left or right position. The attachment of the leaflets to the left ventricular outflow tract is termed an annulus; however, in the strictest terminology, this is not a true annulus because it is not truly circular: the points of attachment of the leaflets do not all lie in the same plane. There are two important surgical landmarks. First, the commissure between the left and noncoronary leaflets is positioned along the area of aortic–mitral valve continuity. Beneath this commissure is the fibrous subaortic curtain. The commissure between the noncoronary and the right coronary leaflets is positioned over the left Bundle of His. Injury to this commissure may create heart block.

INDICATIONS

Aortic Stenosis

The diagnosis and severity of aortic stenosis are determined by echocardiography. The normal aortic valve area (AVA) is approximately 3 to 4 cm², and it has very little gradient across the valve until the AVA has been reduced by approximately one-half. Therefore, the flow velocity across the normal aortic valve (determined by Doppler echocardiography) is ≤1.0 m/s. With mild aortic stenosis, the AVA is decreased to >1.5 cm², and the flow velocity across the valve is increased to 2.5 to 2.9 m/s. Aortic stenosis is considered moderate when AVA is reduced to 1.0 to 1.5 cm², and the flow velocity across the valve increases to 3.0 to 4.0 m/s. Severe aortic stenosis is diagnosed by an AVA <1.0 cm² and a velocity across the valve of >4.0 m/s. When normalized for patient body surface area (BSA), severe aortic stenosis is an AVA ≤0.60 cm²/m².

Over a period of years, the valve progressively narrows. During this “latent” period, patients are typically asymptomatic. However, the progressive narrowing of the valve is not linear; it occurs in an unpredictable, stepwise manner. Patient survival is not significantly diminished until patients develop symptoms. Thereafter, survival is quite limited. The three principal symptoms of aortic stenosis are angina, syncope, and heart failure. With the onset of angina, the mean survival of a patient with aortic stenosis is 4.7 years. Once a patient develops syncope, the mean survival is typically <3 years. Patients with dyspnea and heart failure have a mean survival between 1 and 2 years. Heart failure is the presenting symptom in at least one-third of patients with aortic stenosis. Once a patient crosses the threshold from asymptomatic to symptomatic, approximately 3% to 5% of patients will die within weeks to months. Hence, it is extremely important to accurately identify the presence of symptoms. The presence of symptoms in a patient with aortic stenosis is an indication for an aortic valve replacement (AVR). Management of the asymptomatic patient is discussed below.

Aortic Regurgitation

The diagnosis and severity of aortic regurgitation are also determined by echocardiography. Patients with mild-to-moderate aortic regurgitation are typically asymptomatic and have an excellent prognosis without surgery. Severe aortic regurgitation may produce symptoms of heart failure, and AVR is indicated in the symptomatic patient. The asymptomatic patient is discussed below.

SURGICAL TECHNIQUE

The standard surgical approach for AVR is via a median sternotomy (Fig. 48.1). Cardiopulmonary bypass is established by aortic and right atrial cannulation. After initiation of cardiopulmonary bypass, the aortic root is vented and a left ventricular vent is inserted via the right superior pulmonary vein. If the aortic valve is competent, cardiac arrest may be achieved by antegrade cardioplegia with subsequent administration of cardioplegia in retrograde manner. Otherwise, all cardioplegia may be administered retrograde. The myocardial temperature is monitored in the interventricular septum and kept below 10°C by administration of cold blood cardioplegia every 20 minutes throughout the period of aortic occlusion. I routinely cool the patient to a bladder temperature of 28°C.

There are several important technical caveats. First, it is important to prevent the introduction of air into the left atrium with the insertion of left ventricular vent via the right superior pulmonary vein. This can be done by temporarily pinching the venous line, thereby filling the left atrium with blood. I typically vent the aortic root before placing the left ventricular vent to evacuate any air that might be introduced. Second, the ascending aorta in patients undergoing AVR may be very thin because of poststenotic dilatation, advanced age, annuloaortic ectasia, etc. Hence, aortic cannulation stitches must be placed very carefully to avoid tearing the aorta. I often use felt pledges to reinforce each bite of the aortic cannulation stitches to minimize this problem. Third, when operating for aortic regurgitation, the heart is prone to ventricular fibrillation once cardiopulmonary bypass has been initiated. If the heart fibrillates, the left ventricle will
Fig. 48.1. Operative technique: aortic valve replacement. (A) The initial transverse aortotomy is made 3 to 4 cm distal to the right coronary artery. The valve is visualized, and the aortotomy is extended at least 1 cm distal to the zenith of the commissure between the right and noncoronary leaflets. (B) The aortotomy is extended to the half-way point over the noncoronary leaflet. It is then opened down toward the annulus, stopping at least 1 cm from the annulus itself. (C) The leaflets are removed. (D) The calcified annulus is debrided with a Rongeur. It is helpful to place a small gauze sponge in the left ventricle to help catch any flecks of calcium during the debridement. (E) Interrupted horizontal pledgetted sutures are placed with pledgets in the subannular position. (F) After the sutures are brought the valve sewing ring, the valve is seated and the sutures tied.

immediately distend, which may sometimes be lethal. To avoid this, I avoid systemic cooling until the left ventricular vent has been placed. The heart typically fibrillates soon after the initiation of systemic cooling, at which point I immediately cross-clamp the aorta and administer retrograde cardioplegia.

Once cardiopulmonary bypass has been initiated, the plane between the aorta and pulmonary artery is dissected. This is important to optimize visualization of the aortic valve and to facilitate aortic closure. One of the most important technical nuances of this operation is to identify the surface anatomy of the right coronary artery as it originates from the right sinus of Valsalva. This may be done by gentle dissection of the fat pad overlying the right sinus of Valsalva. One must be sure that the aortotomy is not too close to the right coronary ostium, for the ostium may be damaged or distorted with aortic closure or by the valve itself. Once the origin of the right coronary artery is identified, I mark the aorta with the electrocautery at the point of the anticipated aortotomy, approximately 2 to 2.5 cm distal to the origin of the right coronary artery.

As the patient is systemically cooled, the heart will fibrillate. The aortic cross-clamp is then applied, and cardioplegia is administered.

A small, transverse aortotomy is made at the point of the previously placed mark. Through this initial aortotomy, one may visualize the aortic valve. The aortotomy is then extended transversely across the anterior surface of the aorta. It is important to stay approximately 1 cm distal to the zenith of the commissures of the aortic valve leaflets. Having extended the aortotomy to the patient’s right, once the incision is exactly over the half-way point of the noncoronary leaflet, the aortotomy incision is directed to the axis of the aorta down toward the aortic annulus. This portion of the aortotomy incision should stop at least 1 cm distal to the aortic annulus.

The aortic valve is best visualized with the operating table in a bit of reverse Trendelenburg position and rotated a bit to the patient’s left. Traction sutures are then placed through the top of each commissure and snapped to the surgical drapes. This brings the aortic valve up toward the surgeon. The aortic valve leaflets are then excised with scissors. After the leaflets have been removed, a moist gauze sponge is placed in the lumen of the left ventricle to help catch any small pieces of calcium. A Rongeur instrument is then used to gently debride the annulus of calcium.
During this process, it is helpful for the assistant to follow along with an open-tipped suction catheter to help sweep up any small pieces of calcium. Once the annulus has been sufficiently debrided of calcium, the sponge is removed from within the ventricle, and the lumen of the left ventricle is liberally irrigated with cold saline to flush out any calcium debris. The annulus is then sized.

It is very important not to attempt to place an oversized valve. Regardless of the choice of prosthesis, I routinely implant a valve one size smaller than the patient’s annulus might accept as judged by valve sizers. Horizontal pledgeted mattress sutures are placed in the aortic annulus with the pledgets in the subannular position. Note that the annular size will be somewhat smaller once all the valve sutures have been placed. Therefore, I finalize the choice of valve size only after all the valve sutures have been placed. The aortic valve prosthesis is then brought to the field and the sutures passed through the valve sewing ring. To facilitate symmetrical suture placement, it is helpful to mark the sewing ring in thirds.

Once the sutures are passed through the sewing ring, the valve is seated into the aortic annulus, and the sutures tied. To minimize difficulty in seating the valve, the sutures at each of the three commissures should be tied first. Next, a suture midway between each commissure should be tied. In this manner, the surgeon may be assured that the valve will seat appropriately.

Once the valve is sewn in place, the aortotomy is closed with 5-0 polypropylene sutures in two layers. The first layer is a running horizontal mattress stitch, and the second is an over-and-over running stitch. Once the aortotomy is closed, I routinely administer antegrade cardioplegia in order to test the suture line. It is easier and safer to repair any leaks before removal of the cross-clamp.

In anticipation of removing the aortic cross-clamp, I typically infuse warm blood in retrograde manner. The purpose of this is to flush air out of the coronary arteries and to begin increasing the myocardial metabolic rate before reanimating the heart.

During this infusion, it is helpful to begin de-airing the left ventricle by partial occlusion of the venous line and the resumption of ventilation while the left ventricular and aortic vents are on suction. After the retrograde administration of 500 cm$^3$ of warm blood, I administer warm blood in an antegrade manner until the heart reanimates. With the heart beating, the aortic cross-clamp is removed. With the heart beating, one should assess the adequacy of the de-airing maneuvers by transesophageal echo. The usual maneuvers include filling the heart while on cardiopulmonary bypass, rotating the operating table from right-to-left and Valsalva maneuvers to express air out of the pulmonary veins. Once satisfied that the left heart is completely de-aired, the
left ventricular vent is removed and the patient is weaned from cardiopulmonary bypass.

**SURGICAL OUTCOMES**

According to the Society of Thoracic Surgeons (STS) National Cardiac Surgery Database in 2010, approximately 35,000 valve operations are performed in the United States annually; just over one half are cases of isolated AVR. The operative mortality rate in the STS Database for isolated AVR is approximately 2.6%, and the incidence of stroke is 1.3%. The operative mortality rate for combined AVR/CABG is approximately 6.8%.

Certain patient-specific risk factors markedly increase the odds ratio (OR) of death following AVR. Operative mortality is significantly increased with surgery performed under salvage status conditions (OR 7.12), dialysis-dependent renal failure (OR 4.32), emergency status (OR 3.46), nondialysis-dependent renal failure, and first reoperation (OR 1.70).

**CHOICE OF PROSTHETIC AORTIC VALVE**

The operative risks of cardiac valve replacement are not associated with the choice of prosthesis. Further, the hemodynamic performances of contemporary valves are similar. Traditionally, the choice of aortic valve prosthesis has focused on whether a patient would be committed to the risks of life-long anticoagulation (mechanical valve) or the presumed need for reoperation for structural valve deterioration (bioprosthetic valve). However, this approach is an over simplification and the choice of prosthetic valve must be patient-specific. In addition to appropriate consideration of a given patient's comorbidities, one of the most important considerations is the age of the patient at valve implantation. In this light, it is important to recognize that approximately 80% of all valve replacements in the United States are performed in patients above the age of 60 years. Currently, the use of bioprosthetic valves has risen to 80% of all implanted valves.

Following AVR, the median survival for patients <80 years is approximately 11 years; for octogenarians, it is approximately 6 years. The 10-year survival for patients following AVR ranges from 40% to 70%, with an average in the literature of 50%. The type of prosthesis does not impact survival, but other patient-specific factors such as age at operation and presence or absence of coronary artery disease do impact survival following valve replacement.
Regardless of the type of prosthetic valve implanted, approximately one-third of patients die of valve-related causes. Given that valve-related complications occur at a frequency of about 3% to 6% per year, it is important to ask if the risks in a specific patient may be minimized by the choice of a mechanical versus a bioprosthetic valve. The choice of valve prostheses must be individualized.

Mortality among heart valve recipients is valve-related in approximately 30% of patients. The principal causes of valve-related death following valve implantation include thromboembolism (12%), reoperation (10%), bleeding (4%), and prosthetic valve endocarditis (PVE) (3%). The risk of PVE is not different between mechanical or tissue valves. It is approximately 4% spread over the patient’s lifetime. However, if PVE does occur, it is associated with up to a 50% mortality rate.

The leading cause of valve-related death is thromboembolism. Largely because mechanical valves are thrombogenic, the risk of thromboembolism is greater with mechanical valves. At 10 years following AVR, the risk of thromboembolism is 20% for mechanical valves and 9% for bioprosthetic valves.

Because a mechanical valve obligates the patient to chronic anticoagulation therapy (warfarin sodium), the choice of a prosthetic valve must consider the risks of chronic anticoagulation. The risk of bleeding complications from chronic anticoagulation is between 1% and 2% per year. In fact, 4% of valve-related deaths result from bleeding. Mechanical valves should be avoided in patients with contraindications to anticoagulation because of occupation or because of coexistent medical conditions. Similarly, patients who are medically noncompliant or whose level of anticoagulation may not be closely monitored should not receive mechanical valves.

Ten percent of valve-related deaths result from reoperation. It was traditionally assumed that following implantation of a tissue valve, patients would require reoperation for structural valve deterioration. Mechanical valves were, therefore, recommended for patients with a life expectancy longer than 10 years. This reasoning requires refinement. First, placement of a mechanical valve does not eliminate the potential for subsequent valve reoperation. While mechanical valves will not structurally fail, approximately 10% of mechanical aortic valves require reoperation within 5 to 10 years, primarily for paravalvular leak, endocarditis, or nonstructural valve dysfunction such as scar tissue or pannus in-growth. Second, the structural durability of newer bioprosthetic valves is superior to prior generations of valves. Third, it is now appreciated that on average, patient death (all-cause mortality) occurs prior to reoperation for structural valve deterioration. In fact, the incidence of reoperation for structural valve deterioration of a bioprosthetic valve is <15% for patients older than 60 years.

THE ASYMPTOMATIC PATIENT

Asymptomatic Aortic Stenosis

In general terms, asymptomatic patients do not require AVR. However, some do carry a low but real risk of sudden death. The challenge is the identification of the subset of asymptomatic patients in whom the risk of death is greater if AVR is not performed, or in whom the likelihood of AVR in the near-term is probable.

The Risks without Operation

The risk of sudden death in asymptomatic patients is considered to be quite low. However, in a rigorous study of nonoperated patients with asymptomatic aortic stenosis, the incidence of sudden death was approximately 6%. Further, one must also consider that the mortality is 3% to 4% soon after the onset of symptoms.

Unmasking the Symptoms

Given the patient with significant aortic stenosis by echocardiogram, it is therefore important to determine that the patient is truly asymptomatic. This may be objectively confirmed by exercise stress testing (treadmill). While unnecessary and risky in the symptomatic patient with aortic stenosis, exercise testing has been found safe in asymptomatic patients. A modified Bruce protocol should be employed under careful observation. An exercise test is considered positive if symptoms occur, systolic blood pressure falls by more than 10 mmHg, dysrhythmias occur, or ST segment changes are noted. Given a positive exercise test, the patient should be considered symptomatic and offered surgery. As many as 66% of asymptomatic patients may have a positive stress test.

Outcomes of Those with a Negative Stress Test

Following a negative stress, patients must be closely followed for hemodynamic progression of aortic stenosis. On average, the aortic flow velocity increases by 0.3 m/s per year and the AVA decreases by 0.1 cm² per year. However, the flow velocity is largely dependent upon ventricular contractility and should ventricular function decline, velocity may not change despite a smaller AVA. Further, the rate of progression of aortic stenosis is quite variable, making it difficult to predict the clinical course of a given patient.

Several characteristics have been identified, which help stratify asymptomatic patients. Otto and colleagues identified aortic flow velocity as the most important patient-specific variable. The highest risk group were those asymptomatic patients with an aortic flow velocity of >4 m/s, as only 21% were alive without valve replacement at 2 years.

Patients with “very severe” aortic stenosis are defined as those with a peak aortic jet velocity >5 m/s, a mean gradient >60 mmHg, and a valve area <0.6 cm². Asymptomatic patients with very severe aortic stenosis have a very poor prognosis; with event-free survivals was 64% at 1 year and 36% at 2 years. In the only published direct comparison of surgery and conventional therapy in asymptomatic patients with very severe aortic stenosis, Kang and colleagues examined 197 consecutive patients. Early surgery was performed in 102 patients, and a conventional treatment strategy was followed in 95 patients. In the conventional treatment arm, surgery was deferred until the onset of symptoms. At 6 years, the cardiac mortality rate in the early surgery group was 0%, and 24% in the conventional treatment group. Provided that AVR may be performed with low morbidity and mortality, asymptomatic patients with very severe aortic stenosis should undergo AVR.

In addition to the absolute baseline aortic flow velocity, longitudinal follow-up may reveal patients with a rapidly increasing flow velocity on serial echocardiograms; these patients are at risk for cardiac events. Rosenhek and colleagues noted that among patients who remained asymptomatic, the average rate of progression of aortic flow velocity was 0.14 m/s per year. But among those patients who experienced cardiac events, it was 0.45 m/s per year.

Patient age and aortic valve calcification may also be important. In a study of asymptomatic patients, all of whom had aortic flow velocity >4 m/s, those above age 50 years were much more likely to experience cardiac events in follow-up. Interestingly, in this same group, moderate or severe aortic valve calcification was strongly associated with subsequent cardiac events.

From a practical standpoint, I have found the following helpful. For the patient who appears to be asymptomatic following carefully obtained history, an exercise stress is obtained. Patients with a positive stress test are offered surgery. If the stress
test is negative, I have found the recommendations of the European Society of Cardiology helpful and recommend AVR if the aortic flow velocity is >4 m/s, the aortic valve has moderate or severe calcification and the rate of progression of aortic flow velocity is >0.3 m/s per year. I also recommend AVR if the left ventricular ejection fraction (LVEF) is < 50% as this implies ventricular dysfunction secondary to aortic stenosis.

Asymptomatic Aortic Regurgitation

AVR is clearly indicated in the patient with symptomatic aortic regurgitation. Conversely, the natural history of asymptomatic severe aortic regurgitation is not well defined. Ten years after the diagnosis of severe aortic regurgitation, as many as 75% of patients will have died or undergone AVR. It is now clear that upon diagnosis, certain subsets of asymptomatic patients with severe aortic regurgitation who should be offered AVR. The recommendation for AVR should be based on left ventricular size and function.

There is consensus that the asymptomatic patient with severe aortic regurgitation with subnormal LVEF at rest should undergo AVR. This consensus is based on a 25% progression per year to heart failure or death in these patients. Evidence of left ventricular dilation is strongly associated with progression to heart failure or death; a left ventricular end-systolic dimension >55 mm (or >25 mm/m²) or a left ventricular end-diastolic dimension >80 mm are an indication for AVR. Similarly, if longitudinal echocardiographic follow-up reveals either “rapid” diminution in LVEF or a “rapid” increase in left ventricular dimensions, AVR is indicated. While normal at rest, myocardial performance may be found abnormal with exercise. Hence, exercise stress testing may be used to unmask myocardial contractile dysfunction; a fall in LVEF with exercise >5% is a strong relative indication for surgery.

Chapter 48: Aortic Valve Replacement

LOW-GRADIENT AORTIC STENOSIS

Low-Gradient “Severe” Aortic Stenosis with Preserved Left Ventricular Function

The management of these patients is controversial. Unfortunately, up to 30% of patients evaluated for aortic stenosis are found to have echocardiographic discrepancies among the parameters aortic stenosis. Such patients are found to have an AVA that would be considered severe aortic stenosis, but not severe as judged by mean pressure gradient in the setting of a normal LVEF. The explanation for such discrepancies is unclear. Using retrospective data, some authors have recommended that these patients should undergo AVR, suggesting that such patients have advanced aortic valve disease and left ventricular impairment with a reduced stroke volume. However, this may not be the case.

Jander and colleagues prospectively followed 1,525 asymptomatic patients with low-gradient “severe” aortic stenosis (AVA < 1.0 cm² and mean gradient < 40 mmHg) and 184 patients with moderate aortic stenosis (valve area 1.0 to 1.5 cm² and mean gradient 25 to 40 mmHg). At 46 months of follow-up, there were no differences in valve-related events, major cardiovascular events or cardiovascular deaths. These data suggest that this subset of patients have a prognosis akin to moderate aortic stenosis, and that surgery may be deferred.

Low-Gradient Aortic Stenosis with Left Ventricular Dysfunction

Among the most challenging patients with aortic stenosis are those with a low transvalvular gradient and severe left ventricular dysfunction. Low-gradient aortic stenosis is defined as less than 30 mmHg. Treated medically, the median survival of these patients is usually <2 years; the 1- and 4-year survivals are 41% and 15%, respectively. This subset represents less than 5% of patients with aortic stenosis. The clinical outcomes of AVR in these patients have not been well characterized, but the operative mortality rate for AVR in this group of patients has historically been quite high, leading some authors to recommend against surgery.

When the patient with severe left ventricular dysfunction associated with low-gradient aortic stenosis is first seen, it may be difficult to know if the left ventricular dysfunction is primary or secondary. The pathogenesis of left ventricular dysfunction secondary to aortic stenosis is derived from afterload mismatch. With significant aortic stenosis, the left ventricle compensates for pressure overload by hypertrophy, thereby normalizing wall stress. In this manner, LVEF and cardiac output are initially maintained. When the ventricle is no longer able to compensate for the increased wall stress, left ventricular systolic function declines secondary to afterload mismatch. The transvalvular pressure gradient may be low despite the presence of severe aortic stenosis. Provided the left ventricle still has the ability to contract (contractile reserve), clinical outcomes with AVR are quite good; operative mortality is low, and left ventricular function improves after AVR.

On the other hand, the left ventricular dysfunction may be primary rather than secondary to the aortic stenosis. The dysfunctional left ventricle may be unable to open a mildly calcified aortic valve fully if the stroke volume is significantly decreased. This condition is termed “rela­tive aortic stenosis.” These patients have a cardiomyopathy (ischemic or otherwise) with only mild aortic valve narrowing.

For the surgeon and the patient, the principal questions relate to the risks of an operation and whether the patient will be improved afterward. The answers must rely upon a paucity of data regarding the clinical outcomes of patients with low-gradient aortic stenosis and severe left ventricular dysfunction. Taken together, the available data suggest that patients with low-gradient aortic stenosis and severe left ventricular dysfunction may be stratified according to the severity of aortic stenosis and the contractile reserve of the left ventricle. This can be accomplished with a pharmacological challenge with dobutamine. During an infusion of dobutamine up to 40 μg/kg/min, the hemodynamic response may be monitored by echocardiography or cardiac catheterization. In response to dobutamine infusion, stroke volume and thereby cardiac output should increase, raising the transvalvular gradient. An increase in stroke volume of at least 20% is considered evidence of contractile reserve.

In my own experience, I have come to rely heavily upon the echocardiographic appearance of the aortic valve. If the valve is densely calcified with severely restricted leaflet motion, I feel confident the patient has severe aortic stenosis. Conversely, if the leaflets are not badly calcified, or the leaflet motion subjectively seems better than the patient’s clinical condition suggests, I examine the hemodynamics during dobutamine infusion. A dobutamine stress echocardiogram is useful in two ways. First, if the stroke volume (and thereby cardiac output) increases by at least 20%, the patient has contractile reserve. If the increase in stroke volume is associated with an increase in transvalvular gradient, I feel confident the patient will survive AVR with a postoperative improvement in LVEF and functional status. But if no increase in stroke volume and transvalvular gradient are noted with dobutamine, the patient has no contractile reserve or may not have severe aortic stenosis. AVR is not recommended.
"PROPHYLACTIC" AORTIC VALVE REPLACEMENT

The finding of moderate aortic stenosis in patients undergoing concomitant cardiac operations is not uncommon. Whether or not to replace the aortic valve may be a difficult and controversial decision, particularly in patients undergoing coronary artery bypass surgery. In 1994, Collins and colleagues reported a high operative mortality rate (18.2%) in patients undergoing AVR who had had prior coronary artery bypass surgery. Shortly thereafter, several other groups reported similar results. Following these reports, an international trend toward "prophylactic" AVR began for patients with mild-to-moderate aortic stenosis undergoing coronary artery bypass surgery. The decision to perform a "prophylactic" AVR has always been controversial, and significant variation in the management of these patients continues.

Proponents of "prophylactic" AVR at the time of CABG argue the aortic stenosis will inevitably progress, committing the patient to a second operation associated with a high morbidity and mortality. Those favoring an expectant approach argue that "prophylactic" AVR unnecessarily commits an unacceptable number of patients to the risks of valve-related morbidity and mortality. While progression from asymptomatic to symptomatic aortic stenosis in a relatively short time is clinically recognized, it is very difficult to identify those patients likely to do so. At the heart of the argument is the need for an understanding of the natural history of mild-to-moderate aortic stenosis and the contemporary risks of AVR after previous CABG.

The natural history of moderate aortic stenosis (AVA 1.0 to 1.5 cm²) is difficult to define but is clearly worse than that of mild aortic stenosis. Rosenchek and colleagues reported an ominous natural history for patients with moderate aortic stenosis (aortic flow velocity 2.5 to 3.9 m/s). Of 176 patients followed for an average of 48 months, 33 underwent AVR and 34 patients died. The 5-year event-free survival was 60%. The strongest predictors of patient events were aortic valve calcification, a peak aortic flow velocity at study entry >3 m/s, age >50 years, and coronary artery disease. The data from Rosenchek are consistent with those of Otto and clearly indicate that patients with moderate aortic stenosis may experience hemodynamic progression during relatively short follow-up.

The operative mortality rate reported for AVR subsequent to CABG has significantly diminished in recent years. Certainly advances in myocardial protection, surgical and anesthetic techniques as well as greater collective experience with cardiac reoperations have contributed to improved outcomes. In recent series, the mean interval between CABG and subsequent AVR is typically 7 to 9 years. In these reports, the operative mortality rate of the AVR at reoperation has been approximately 7% and not significantly different from the operative mortality associated with AVR/CABG done in the same institutions, suggesting that an expectant approach is warranted.

Smith and colleagues utilized the STS National Cardiac Surgery Database and employed Markov decision analysis to analyze quality-adjusted outcomes of patients with mild-to-moderate aortic stenosis undergoing CABG alone versus CABG/AVR. Assuming a constant rate of progression of aortic stenosis of 5 mmHg/year, the authors concluded that "prophylactic" AVR may be indicated in all patients once the valve gradient exceeds 28 mmHg. However, in patients above the age of 70 years, the threshold to "prophylactically" replace the valve steadily rises; the morbidity of AVR plus CABG is higher than with CABG alone. Dagenais and colleagues reported that in patients >70 years with moderate aortic stenosis, the operative mortality of AVR/CABG was not different than CABG alone. But the incidence of perioperative neurological injury, mediastinitis, and renal failure were all significantly higher. Further, there was no difference in at 5-year survival.

Patients with mild AS at the time of CABG (AVA >1.5 cm²; aortic flow velocity <2.5 m/s) have an excellent prognosis from their aortic valve and should not have AVR. On the other hand, patients above age 65 years who undergo CABG with moderate aortic stenosis and an AVA <1.2 cm² and/or an aortic flow velocity >3 m/s associated with significant aortic valve calcification are likely to have symptomatic aortic stenosis within the next several years. In this subset of patients, it is reasonable to perform AVR with CABG at the initial operation.

AORTIC VALVE REPLACEMENT WITH A PATENT INTERNAL MAMMARY

AVR in patients who have had previous coronary artery grafting, particularly if the internal mammary artery (IMA) graft is patent, can be technically challenging. It is associated with mortality rates of 6% to 17%, considerably higher than first-time AVR procedures. Contributing to this mortality rate is the fact that the IMA may be damaged during the procedure, or its presence may compromise myocardial protection during the procedure.

To minimize the risk of injury to the IMA, some advocate moderate-to-deep systemic hypothermia (20°C) while on cardiopulmonary bypass, aortic occlusion, administration of cardioplegia, but avoidance of dissection of the IMA pedicle. Others also leave the IMA open during the period of aortic occlusion but administer continuous retrograde cardioplegia. With either technique, flow through the IMA may washout cardioplegia and warm the heart during the procedure. A third option is to utilize deep hypothermia and circulatory arrest.

While these techniques may be helpful in situations in which the IMA is densely adherent to the posterior sternum and cannot be safely dissected, it is preferable to dissect out the IMA and occlude it during aortic cross-clamping. The IMA may be isolated even before re-sternotomy using a supraclavicular incision. With interruption of IMA flow, the surgeon may be confident that cardioplegia will not be washed out and the heart will be made uniformly cold.

It may also be difficult to expose the aortic valve through the standard aortotomy because of the presence of saphenous vein grafts anastomosed to the proximal aorta. In my own practice, I have found it helpful to cannulate the axillary artery in these cases. In so doing, the aorta may be cross-clamped just proximal to the innominate artery, which provides several more centimeters of ascending aorta unencumbered by the aortic cannula. This extra length of ascending aorta then permits an aortotomy incision (which avoids proximal anastomoses) made in the axis of the aorta, directed posteriorly along the patient’s right. Excellent exposure of the aortic valve is achieved without injury to previously placed proximal anastomoses.

THE SMALL AORTIC ANNUlus

The use of all mechanical and stented bioprosthetic valves results in some degree of residual obstruction to flow because of the sewing rings and stents. Nonetheless, the goal of AVR is to leave the patient with minimal gradient across the valve. In so doing, the increased left ventricular mass index (developed in compensation for aortic stenosis) typically resolves following aortic valve replacement. Traditional concern has surrounded the potential for a high residual transvalvular gradient should too small a prosthesis be implanted, creating
the phenomenon of “prosthesis–patient mismatch” (PPM). The term “prosthesis–patient mismatch” was coined in 1978 by Rahimtoola and used to describe his observation that a patient’s aortic stenosis may not be completely relieved by a prosthesis. This concern has led to a persistent controversy over the management of the small aortic annulus.

While some authors have demonstrated that implantation of small aortic valve sizes has no effect on long-term survival, others have suggested otherwise. One factor confounding the interpretation of these data is the fact that the sizing of prosthetic valve is inconsistent from one manufacturer to the next. Depending on the manufacturer, a size 19 valve may vary in effective orifice area (EOA) from 1.0 to 1.3 cm². Another confounding factor is the fact that population of patients (with particular regard to patient age, gender, and size) has varied from one report to the next.

The patient’s size (BSA) and age must be considered when choosing the appropriate aortic valve prosthesis. Acknowledging some of the uncertainties provided by the literature in this area, one should avoid implantation of an aortic prosthesis with a calculated EOA/BSA <0.8 cm²/m²; it is generally accepted that the likelihood of PPM is minimized if the prosthesis provides the patient with an EOA/BSAi >0.85 cm²/m². An EOA/BSAI of 0.65 to 0.85 cm²/m² is considered moderate PPM, and <0.65 cm²/m² is considered severe PPM. This recommendation is derived from the fact that an AVA of 0.6 cm²/m² is considered severe aortic stenosis. The use of this guideline is helpful as it places the consideration of valve size in the context of the patient’s hemodynamic needs, rather than in absolute terms.

The implication of this strategy is the anticipation that the patient with a larger BSA will require a higher flow rate across the valve (cardiac output) than will the patient with a smaller BSA. Knowledge of the patient’s BSA and the EOA of given sizes of a particular type of prosthesis permits an estimation of the valve size needed to leave the patient with an appropriate EOA/BSA ratio. Since PPM may not affect a difference in survival for 5 to 7 years other patient-specific factors must be considered such as age and activity level; the 60-year-old distance runner will require a larger EOA than the 80-year-old sedentary person. Nonetheless, this strategy serves as a useful guideline in choosing valve size.

The problem of the large valve relative to the small aortic annulus has plagued cardiac surgeons since the outset of aortic valve surgery. Within a few years of the first AVR by Harken in 1960, surgical techniques to surmount the problem by enlargement of the annulus emerged. By the end of the 1970s, Nicks, Konno, and Manouguian had each described techniques to enlarge the annulus in order that a larger valve may be implanted. Nicks (1970) and Manouguian (1979) each described techniques of patch enlargement of the posterior aspect of the aortic annulus. Konno described a more extensive procedure of aortoventriculoplasty of the anterior aspect of the aortic annulus in 1975. More recently, Otaki described a method of patch enlargement of both the posterior and anterior aortic annulus (1997).

Implantation of stentless bioprosthetic aortic valves was reported by 1990. Without the valve struts of their stented counterparts, the design of stentless valves offers an inherently larger EOA. In most centers, stentless valves are implanted by one of the two techniques: subcoronary or as a total aortic root replacement. While some controversy exists in the literature, it is generally accepted that the hemodynamic performance of stentless bioprosthetic valves is better than that of stented valves. In particular, the use of the root replacement technique is felt to minimize the risk of PPM.

Patch enlargement, stentless valve, and the Konno procedure may all be used effectively to avoid PPM. In my opinion, posterior patch enlargement of the annulus is the easiest and most straightforward technique. According to the STS National Cardiac Surgical Database, approximately 2.4% of AVR procedures performed in 2010 included an annular enlarging procedure. Early concerns were expressed that operative mortality was higher with the use of the technique, and it was therefore avoided by many. Contemporary experience, however, demonstrates that surgical outcomes are probably not different from those of AVR alone. The annular dimensions should be known from the preoperative echocardiogram, allowing the surgeon to plan to enlarge the annulus from the outset of the procedure. As a rule of thumb, a Nicks procedure (incision of the annulus in the mid-point of the noncoronary leaflet portion of the annulus) will generally permit one-size larger valve. On the other hand, a Manouguian procedure (incision of the annulus through the commissure of the non- and left valve leaflets) will generally permit the placement of a valve two sizes larger. In my experience, a Nicks procedure is typically sufficient and therefore my preferred technique (Fig. 48.2):

1. Enlarge the annulus at the midway point of the noncoronary leaflet. This is accomplished by extension of the aortotomy incision.
2. Extend this incision into the fibrous apron between the mitral and aortic annuli, but it is unnecessary to incise the mitral annulus or the anterior leaflet of the mitral valve.
3. Beginning at the apex of the incision, a fashioned piece of woven Dacron is sewn in place. The patch material is typically 2 cm wide, and beveled at the point of insertion into the annulus. A pledged 5-0 polypropylene suture is brought through the patch material, next the roof of the left atrium, and then the apex of the aortic incision, and tied. The patch material is sewn to the aorta for a distance of about 2 inches. I always use a second suture line of 5-0 polypropylene suture to aid with hemostasis.
4. The valve sutures are placed. In the area over the patch material, four pledged sutures of 4-0 polypropylene suture are brought from outside-in through the patch material.

Technical Caveat: If the patch material is too wide over the anterior aorta, the proximal aorta may be displaced anteriorly. In so doing, the orifice of the right coronary may be displaced and kinked. This may be avoided by cutting the patch material no wider than about 1.5 to 2 cm in this area. Should the right coronary artery ostium be distorted despite this, the patch material may be imbricated anteriorly in order to restore the normal position of the right coronary artery ostium.

6. Once the aorta is closed, test for hemostasis by administration of antegrade cardioplegia. A small amount of oozing through the patch material is to be expected until heparin reversal. But any bleeding sites, particularly near the apex of the patch closure, should be repaired before release of the aortic cross-clamp.
Fig. 48.2. Operative technique: aortic annulus enlargement. (A) The aortotomy incision is extended across the aortic annulus at the midpoint of the noncoronary leaflet. (B) Vascular patch material is partially sewn in place. (C) The valve is implanted. Across the patch material, the pledgeted valve sutures are placed from “outside-in.” (D–F) The patch material is brought anteriorly to close the aorta.
THE PORCELAIN AORTA

The presence of extensive, dense calcification of the aortic root and ascending aorta complicates a small but important percentage of patients undergoing AVR. In the setting of a porcelain aorta, AVR using the standard technique and aortic cross-clamp results in an unacceptably high risk of stroke and death. It may, in fact, be a contraindication for surgery in some patients. Hence, alternative surgical strategies must be utilized.

Hypothermic Circulatory Arrest

Peripheral arterial cannulation via the right axillary artery and the use of deep hypothermia and circulatory arrest without aortic cross-clamping can be an effective strategy for AVR with possible aortic replacement. Cosselli first described AVR using circulatory arrest in 1986, and Byrne likewise reported its use in 1998. Both reported excellent outcomes in a total of five patients. It may, in fact, be necessary to completely excise a badly calcified aortic root, and Wareing and colleagues first described aortic replacement under circulatory arrest in 10 patients in 1992. The operative mortality was 10%, and no patients sustained a stroke. More recently, Girardi and colleagues reported their experience of aortic valve and aortic replacement in 25 patients under circulatory arrest. The operative mortality was 8% and the incidence of stroke was 4%. In the opinion of this author, this is the preferred strategy. Right axillary artery cannulation provides the ability to employ selective cerebral perfusion during the period of circulatory arrest. Replacement of the calcified aorta obviates the need to perform aortic endarterectomy in order to secure aortic closure. Both operative mortality and stroke are acceptably low with the use of the technique.

Aortic Valve Bypass

Aortic valve bypass with the use of an apical–aortic conduit was first used clinically in 1962. It was reintroduced by J.W. Brown with a report of 23 patients in 1984. The technique is not commonly utilized, as fewer than 200 patients have been reported in the literature. Significant aortic regurgitation is considered a contraindication to the procedure. The procedure may be performed with or without the use of cardiopulmonary bypass, but in the experience of this author, the procedure is greatly facilitated by its use. As described by Gammie...
Fig. 48.2. (Continued) and colleagues, the procedure is performed through a left anterior–lateral thoracotomy incision. A valve-conduit is placed from the left ventricular apex to the descending aorta. The valve-conduit consists of three parts: a rigid apical connector, a stentless porcine aortic root, and a prosthetic graft. The three parts are sewn into continuity on the back table of the operating room. The use of a prosthetic graft with an 8 mm side branch permits arterial cannulation for cardiopulmonary bypass through the side branch. Success of the procedure requires that the apical connector be securely placed within the left ventricular apex, as the apex may be friable. This is best accomplished by full thickness bites through the ventricular muscle. Failure to securely place the apical connector may result in significant bleeding or pseudoaneurysm formation. As the prosthetic graft is anastomosed to the descending aorta, it is very important to be certain that the valve conduit will lay in a manner that will not be kinked and that its length is appropriate.

Using this technique in 47 high-risk patients, Gammie and colleagues recently reported an 11% operative mortality. The incidence of stroke was 6%. Blood flow through the valve-conduit was found to be a mean of 60% of total cardiac output. Survival at 1 year was approximately 70% and approximately 50% at 2 years. However, given the small number of patients that have undergone the procedure, the durability of the procedure is not well characterized.

SUGGESTED READINGS

EDITOR’S COMMENTS

The chapter on Aortic Valve Replacement by Dr. Fullerton is truly a complete and learned discussion of this very common part of cardiac surgery. I agree with virtually everything with some minor acceptations. I agree that the technical aspects of this valve replacement are critically important. One should truly avoid impingement of the coronary ostia. There are some surgeons who enlarge the aortic root frequently and I believe our philosophy is closer to Dr. Fullerton’s to enlarge less frequently. It makes no sense to put a large valve in a very small elderly patient.

The only minor disagreement we have is handling the patent internal mammary artery bypass in a reoperative situation where valve replacement is necessary. We have published that attempting to find the internal mammary in order to control it occasionally leads to injury of this important blood vessel. We, therefore, prefer now to use moderate hypothermia and intermediate cardiologic just as we do in every case and leave the internal mammary artery flowing. We have incurred extremely low mortality in this situation and little evidence that we create any LV dysfunction. In fact, mortality for redo aortic valve operations with patent coronaries is in the 2% range.

This is truly an excellent chapter. I think that Dr. Fullerton gives a great amount of detail about techniques to use in some really complex situations.

ILK
The Ross procedure, first performed by Mr. Donald Ross in 1967, is the replacement of the aortic valve with the autologous pulmonary valve. It is considered the valve of choice for aortic valve replacement in children. It is also ideal for replacement in younger patients, athletes, women of child-bearing age, and patients with endocarditis. The operation since 1967 has evolved with better standardization of techniques and in multiple long-term studies has produced similarly excellent results.

**INDICATIONS**

Patients with a life expectancy of more than 20 years are candidates for the Ross procedure. Likewise, patients who cannot safely take or have a lifestyle not desirous of permanent anticoagulation are candidates for the procedure. Athletes whose sport requires extended periods of highly elevated heart rates will also see better performance with an autograft than a mechanical valve. Over the last 20 years, the Ross procedure has proven highly effective for aortic endocarditis. The autograft, with the flexibility of tissue and used as a root, allows for increased cure of the infection and has better longevity than other valve choices. Initially, discrepancy in aortic annulus to pulmonary annulus size was a contraindication. With improved techniques of dealing with the enlarged aortic annulus, reduction and fixation in a size suitable to the recipient, the Ross procedure is now performed in these patients. In the pediatric age group, the Ross procedure can be combined with the Konno procedure (myotomy and myectomy), particularly useful in combination with left ventricular outflow tract (LVOT) obstruction with aortic stenosis. An extension of right ventricular outflow tract (RVOT) muscle can be harvested with the autograft to fill in the myotomy for the enlargement of the LVOT. The viability of this graft then allows for continued growth with the child.

**CONTRAINDICATIONS**

Patients with Marfan’s or other genetic disorders known to affect fibrillin or elastin of the aortic valve are not candidates for the Ross procedure because the pulmonary valve is likely to be affected by the same disease process. This includes patients with bicuspid aortic valve associated with root enlargement. Patients afflicted with significant immune-complex disease (juvenile rheumatoid arthritis, lupus erythematosus, and active rheumatic heart disease) as the etiology of their aortic valve disease have had early failure or degeneration of the pulmonary autograft valve. These patients are not considered candidates for a Ross procedure. In general, patients who fall into these categories have had early failure of the autograft through dilatation of the root into an aneurysm and/or development of aortic insufficiency.

**SURGICAL TECHNIQUE**

A standard median sternotomy is recommended, as adequate exposure of the great vessels and roots is mandatory for safe harvesting of the autograft and implantation of the coronary ostia. The operation then proceeds as for an aortic valve replacement. Cannulation high on the aorta is done in case remodeling or rescission of some of the ascending aorta is necessary. Either bicaval venous cannulation or two-stage single venous cannulation is acceptable; however, care must be taken to avoid air lock in the venous return when the RVOT is opened. Antegrade cardioplegic and aortic sump line is placed as well as retrograde coronary sinus cannula for intermittent or continuous retrograde blood cardioplegia. Manipulation of this cannula can be facilitated by the echocardiographer without having to open the aorta. A left ventricular sump is placed via the right superior pulmonary vein (Fig. 49.1). As cardiopulmonary bypass is begun, dissection between the great arteries is performed until the take-off of the right pulmonary artery is seen. Systemic cooling is accomplished to 32°C to 34°C. With aortic clamping antegrade followed by retrograde blood cardioplegia is delivered for complete arrest. This is facilitated with saline slush in the pericardial well. Initially, the autograft is harvested by making a transverse arteriotomy proximal to the right pulmonary artery take-off (Fig. 49.2). Inspection of the valve leaflets is done to rule out a dehiscence (bicuspid or fused) in the pulmonary valve (Fig. 49.3). A bicuspid pulmonary valve should not be used. Finding this, one would abort the Ross and use the backup valve planned with the patient preoperatively. The cryopreserved pulmonary homograft can then be thawed, so it will be ready for implantation later. The harvesting of the autograft is begun posteriorly using the electrocautery. One must dissect close to the pulmonary artery. Caution is taken as the left main coronary artery lies posterior and superior at the base of the pulmonary artery. Dissection is carried down to the level of ventricular muscle (Fig. 49.4). A right-angled clamp is then placed through the opening of the pulmonary valve visualizing the RVOT muscle beneath the annulus. The clamp can then be pushed through the muscle about 3 to 4 mm from the annulus (Fig. 49.5). From this opening, sharp dissection is accomplished with scissors and direct visualization of the annulus. Three millimeters of subannular muscle is taken with the graft. Initial dissection is to the patient’s left to the point where the posterior wall of the RVOT begins. Similarly, the dissection is taken to the patient’s right, again to the posterior wall. Scalloping the underlying muscle is useful always maintaining the same 3 to 4 mm of muscle (Fig. 49.6). The posterior wall is incised with a scalpel and dissection is carried to a depth in the muscle similar to the thickness of the RVOT muscle cut through anteriorly. Embryologically, the RVOT is separate.
Section II: Adult Cardiac Surgery

**Fig. 49.1.** Cannulation: Distal aorta, bicaval cannulation with the superior vena caval cannula placed through a purse string in the vena cava, the left ventricular vent through the right superior pulmonary vein, and the retrograde cardioplegia cannula through the right atrium. All illustrations are oriented as seen by a surgeon standing on the right side of the patient.

**Fig. 49.2.** The distal pulmonary artery is incised at the origin of the right pulmonary artery. A transverse arteriotomy is made that is adequate for careful inspection of the pulmonary artery.

from the septal muscle and this plane can be seen as one dissects directly posterior. When this plane is reached, care must be taken to avoid the first septal perforator which runs in this layer. The most common course of the artery is from the anterior descending coronary to the middle papillary muscle of the tricuspid valve, which is easily visualized. The angle of dissection is changed to be more horizontal and is carried craniad until the level of the previous posterior dissection is reached. This is the enucleation of the valve. Caution around the sinuses is important as too close dissection may injure the sinus wall. The valve can then be inspected for injury and then placed in the pericardial well for safe keeping. This harvested valve can later be used as a subcoronary (scalloped) valve or as a root.

**SUBCORONARY IMPLANTATION**

Most surgeons now use one of the two techniques for the implantation of the autograft. The subcoronary technique, Mr. Ross’ original technique, uses a hockey-stick aortotomy. The aortotomy is started 2 to 3 cm above the right coronary ostium and angled down into the noncoronary sinus. The aortic valve is excised and the annulus sized. The autograft is then trimmed of excess epicardial fat and tissue, and the subannular muscle is trimmed to 2 to 3 mm. The sinuses of what will be the left and right sinus of the autograft are excised leaving 2 to 3 mm of arterial wall above the annulus. The distal artery is trimmed to just above the commissures. This leaves the noncoronary sinus intact. Implantation is accomplished by interrupted 4-0 polypropylene sutures or in running single or triangulated-running suture. The triangulation is done by placing three separate sutures through the aortic annulus and in the subannular autograft at the nadir of the cusp. Interrupted sutures are then placed at 2 mm separation between the triangulated sutures. Some surgeons will reinforce this proximal suture line with a strip of autologous pericardium. If a running triangulated suture technique is used, each suture can then be run to the commissures. Similarly, a single running suture can be done from the nadir of the left cusp (beneath the left coronary ostium) and run first counterclockwise to the right noncommissure followed then by the other end of the suture run clockwise to meet the suture at the right noncommissure. Some surgeons facilitate the exposure by inverting the autograft valve into the LVOT. As the muscle of the autograft was somewhat scalloped with the harvesting, the line of the anastomosis will follow the natural annulus. With the proximal anastomosis completed, the distal implant is accomplished with a running 4-0 polypropylene suture. The right–left commissural post is tacked to the wall 3 to 5 mm above the existing native commissure. It is important to have the post in this suspended position as laxity will result in prolapsing of the leaflets. The noncoronary sinus maintains the relation of its connected commissural posts at 120 degrees. Tacking of the other posts is facilitated by leaving the noncoronary sinus intact. The suture line proceeds in scallop manner beneath the coronary ostia attaching the autograft to the sinus walls in a hemostatic manner. The noncoronary sinus is tacked to the remaining aortic wall to remove any free space behind it. Closure of the aorta then incorporates aorta to autograft in a manner as to not buckle
the noncoronary sinus of the autograft. Advantages of this implantation technique include not having to reimplant the coronary ostia and avoidance of late sinus dilation as may be seen with the root technique. Disadvantages include inability to perform if there are dilated sinuses and inability to do if calcifications exist in the sinus walls prohibiting the suturing in the wall of the sinus. Groups with long-term results using this technique have achieved similar results with those surgeons using the root implantation technique.

**ROOT IMPLANTATION**

The root implantation technique has become the most popular for insertion of the pulmonary autograft. It is easier to insure a competent aortic valve as no manipulation of the commissural posts is required. Since beginning the use of the Ross procedure, we have exclusively used this technique. Patients with dilated sinususes, dilated sinotubular junction, true bicuspid valve with 180-degree coronaries are all candidates for a root replacement. Cannulation is the same for the root replacement as with the subcoronary technique. Bypass and autograft harvesting are likewise the same. Preparation of the autograft is different as the adventitia is left intact but the muscle below the annulus is trimmed to 2 to 3 mm. The aorta is transected at the sinotubular junction with dissection of tissue behind the aorta to enter the transverse sinus. The aortic valve is excised and the annulus measured. Each coronary ostium is excised with a portion of aorta creating "buttons" that will be reimplanted later into the autograft. Mobilization of each ostium is important to allow for proper reimplantation. The noncoronary sinus is left intact and not excised. This will be used as reinforcement to the root in patients who have a dilated annulus, dilated sinuses, or sinotubular junction. If the patient has aortic insufficiency or has an annular size larger than the normal aortic size for the patient’s body surface area, an annular reduction and fixation is accomplished using a double row of 2-0 polypropylene placed in an intra-annular plane and brought to the outside of the noncoronary cusp for tying through a pledget. This double row of suture run in purse-string manner can then be tightened over a sizer to achieve the desired annular size for the specific patient (Fig. 49.7). Aortic stenosis patients without annular enlargement have not required the fixation and do not require the use of the native noncoronary sinus. The proximal anastomosis is then performed as described with the subcoronary implantation technique. If annular fixation is used, then the suture line must incorporate the fixing sutures. The autograft is oriented so that the posterior sinus of the pulmonary valve will be the left coronary sinus in the root. This positions the autograft in the most anatomic position. We have used the single running technique almost exclusively. It is paramount to visualize each suture placement to avoid placing a suture into the annulus or the leaflet. The sutures should be placed in a tangential manner from endocardial muscle angled to a higher level exit on the epicardium, in line with the annulus. This telescopes the autograft annulus into the remaining native aortic annulus. The suture line is reinforced with a thin strip of pericardium, which acts as a hemostatic gasket. Inspection of the leaflets following the anastomosis insures no injury to the leaflets. Should a suture be placed in a leaflet, it must be removed and replaced as eventual perforation of the leaflet will occur. An incision is made in the left sinus and enlarged with an aortic punch. The left coronary button is then sewn to the opening, without rotation, using 5-0
Section II: Adult Cardiac Surgery

Fig. 49.5. Identification of the anterior right ventriculotomy is facilitated by placing a right-angled clamp through the pulmonary valve and indenting the myocardium 3 to 4 mm below the pulmonary valve annulus.

Fig. 49.6. Completion of the posterior enucleation of the pulmonary autograft from the outflow tract of the right ventricle. Note the usual location of the first large septal perforating coronary artery. It arises adjacent to the first diagonal coronary artery of the left anterior descending coronary artery and traverses the septal musculature toward the conal papillary muscle of the tricuspid valve.

polypropylene running suture (Fig. 49.8). Excellent hemostatic suturing is helpful as this is difficult to see after distention of the aorta. Inspection is made from the interior also. The autograft is then trimmed so only 2 to 3 mm of artery remains above the commissures. Marking of the commissures on the outside of the autograft will facilitate the placement of the right coronary after the distal closure of the autograft to the aorta. The distal anastomosis is then performed between the autograft and ascending aorta. It is this suture line that the remaining noncoronary sinus of the native aorta can be attached in patients with insufficiency. The reinforcement covers the most vulnerable portion of the root for dilation. The left sinus is protected by the left atrium and a portion of the right by the pulmonary homograft. In addition, the left and right sinuses will have the coronary ostia implanted to help reinforce them. It is our feeling that aortic stenosis patients are not at the same risk of late dilation. If annular downsizing has been used, it is important to make the sinotubular (distal) anastomosis the same size as the annulus. Example: 23 mm annulus = 23 mm sinotubular junction. This can be accomplished by ascending aortoplasty (by posterior wedge resection) or interposition of Dacron graft. This insures against late dilation at the sinotubular junction with ensuing aortic insufficiency. With completion of the distal anastomosis, the aortic clamp, with low flow in cardiopulmonary bypass, can be temporarily released to allow for distention of the root. The mobilized right button can then be measured to a high position on the right sinus and a hole made where the implantation will take place. The previous commissural markings on the exterior will help to not injure the leaflets, which will be coapted with the aortic pressure. The hole is enlarged with an aortic punch. Rotation of the right coronary button is more of a risk than with the left and must be avoided. Placement in a higher position in the sinus also avoids kinking of the artery with distention of the right ventricle.

RIGHT VENTRICULAR OUTFLOW RECONSTRUCTION

Replacement of the “switched” autograft has been with a pulmonary homograft in our experience. There are reports of heterograft and aortic homografts being used, but most surgeons performing the Ross procedure choose a pulmonary homograft. There is evidence of better performance than with the other choices. More recently, decellularized pulmonary homografts have been used with good success. The repopulation with native endothelium into the decellularized matrix remains a question. We have had success with both grafts. We universally choose a homograft that is 2 to 3 sizes larger than the size of a normal aortic valve size for the patient. Example: 23 mm aortic valve = 27 to 28 mm pulmonary homograft. We believe that this is responsible for our very low incidence of homograft explant secondary to late pulmonary stenosis. Some surgeons will attempt the reconstruction with the cross-clamp off. We have found that with the safety of modern cardioplegic techniques that a dry motionless field actually speeds the operation. The thawed homograft is trimmed to mimic the excised autograft. Generally, the main pulmonary artery is transected proximal to the bifurcation and the excess RVOT muscle is trimmed to 4 mm below the annulus. The distal anastomosis is performed first using 4-0 polypropylene. Care is taken not to narrow the anastomosis. A finger can then be passed into both the right and left pulmonary arteries through
the valve. Lastly, the proximal anastomosis is performed with 4-0 polypropylene. Hemostasis in the bed of the enucleated autograft is paramount prior to the proximal closure. Electrocautery and possibly sutures can insure this. One must insure not to rotate the valve and suturing is best started at the patient’s left side of the RVOT. There are trabeculations in this region that require accurate closure. The suture line then proceeds on the posterior wall with tangential sutures so as to not injure the first septal perforator. The anterior running closure then follows (Fig. 49.9). Care must be taken on the left side to not take too much tissue in the suture that could damage the left anterior descending artery. Following rewarming, which is done while the homograft is placed, the cross-clamp is released and de-airing accomplished. Usual weaning from cardiopulmonary bypass is then accomplished. Transesophageal echocardiography is then performed to evaluate the neoaortic valve. It is typical to see a small central insufficiency jet. Finding significant insufficiency warrants investigation into source, whether prolapse of leaflet or rotation of graft.

**POSTOPERATIVE MANAGEMENT**

Postoperative management of the patient actually begins in the operating room. Management of the aortic blood pressure is paramount. We keep the pressure <110 systolic and lower if tolerated by the patient. This continues throughout the stay in the ICU with IV drips. When the patient tolerates oral intake, oral antihypertensives are added to the regimen. As these are generally younger patients, the lower blood pressure is nicely tolerated. We try to manage the
Since 1967, the Ross procedure has undergone multiple variations in the technique of implantation and indications for use. We have also learned some contraindications. Each modification has been added or deleted in an effort to improve the long-term outcomes, or to facilitate the ease of performing the operation. Following Mr. Ross’ publication of his 20-year results, there was a sharp increase in the number of cases performed. Not all were performed in the same technique with many variations of autograft implantation used. Some of the variations were useful while others were not so well-performed. However, the results of the multiple changes were all reported as Ross procedures. This has allowed for variations in outcomes as one would expect. Many of the changes, when followed over the years, have added to better results. These many variations early in the history have led to poorer acceptance of the procedure. Those who have persisted with sound autograft techniques with long-term follow-up have had very good results, which are duplicated by the other programs following similar techniques. Through accurate clinical follow-up, progress has definitely been made in delineation of appropriate and inappropriate candidates. Technical features such as reduction and fixation of the aortic annulus with concomitant fixation of the sinotubular junction have blood pressure for a minimum of 3 months. Should the patient have hypertension, a lifetime management is very important. We strongly believe that this has led to a lowered level of late dilation and valve incompetence. Another postoperative management is the addition of anti-inflammatory medication, usually in the form of nonsteroidals. The pulmonary homograft can cause an intense postpericardiotomy syndrome, and the addition of these drugs may help prevent some immune responses, which could lead to homograft constriction. This phenomenon is also helped by the oversizing of the homograft as was described in the technique section of homograft implantation. The nonsteroidals can be discontinued in 3 to 4 weeks.
been extremely beneficial. Postoperative management of blood pressure and use of anti-inflammatory drugs have boosted long-term results in the series that have incorporated this protocol. The use of the Ross procedure in endocarditis has produced outstanding results in cure rate and re-infection rates and provides the patient with a valve that has significantly better longevity than other valves. The viability of the autograft, with cellular levels of preoperative antibiotics, insures increased cure rates when placed in an adequately debrided LVOT. Placement as a root completely exteriorizes to the pericardium space all infection leaving none exposed to the endothelium and blood stream. The flexibility of the graft allows for modeling of the valve to the irregularities of the debrided annulus, thus providing a more secure hemostatic anastomosis. Flexibility rather than rigidity, as with a stented bioprosthesis or mechanical valve, markedly decreases the incidence of late paravalvular leak or pseudoaneurysm. When compared in a prospective randomized study, the autograft has outperformed the aortic homograft in both earlier valve failure and mortality rates. With improved cardiopulmonary techniques, the use of the Ross procedure for endocarditis, while requiring possibly longer ischemic times, has not lead to any unfavorable outcomes.

Our series of Ross patients began in 1989. Since then, 386 patients aged 1 day to 71 years, mean age 39.6, follow-up range 0 to 19 years have undergone a root replacement with the autograft. The operative mortality was 4.1%. Kaplan–Meier survival at 15 years is 86%. Freedom from explant of the autograft is 71% and freedom from pulmonary homograft explant is 93%. In our cohort of patients with a mean age of 55 years, freedom of mortality was 85%. Programs that have performed the Ross procedure for more than 15 years all show very similar survivals and reoperation rates, both in the United States and Europe (Table 49.1). Comparison to other valve series, with similar or longer length of follow-up, in mechanical valves, bioprosthetic valves, and homografts are shown (Tables 49.2 to 49.6). Each of these series have a mean age of 50 years or greater, similar to the Ross series. Although cross-comparisons may be difficult, a definite difference in survival rates is seen. The final table groups the valve series in survival percentages for comparison (Table 49.7). Besides the follow-up data presented, there remains the subjective advantages to the Ross procedure. There is a profound lack of thromboembolism throughout the life of the patient as well as the freedom of frequent and inconvenient management of anticoagulation in a patient with a mechanical prosthesis. The option of child-bearing in women of this age group is extremely important. We have many patients who have born children post-Ross procedure. There is no noise related to the autograft, and the physiologic function and ventricular remodeling have been well documented.

The Ross procedure remains an excellent procedure for aortic valve replacement. Proper selection of candidates is mandatory and performance of an exact operation allows for excellent outcomes. More than other procedures, attention to postoperative management needs to be in the surgeon's control. It is the valve of choice for the pediatric age group and a good choice for patients of child-bearing age, athletes, patients with endocarditis, and patients who must avoid anticoagulation.

**SUGGESTED READINGS**

This is a chapter by Chip Oswalt, who is one of the experts at the Ross procedure. He has published extensively on endocarditis. We too use the Ross procedure though our uses are more limited than they have been previously. As Dr. Oswalt has mentioned, patients with bicuspid valves and with aortic dilation often go on to develop ascending aneurysms late. We have seen this. In the vast majority of these situations, we have been able to preserve the autograft but this is a significant complication of the Ross procedure. We now reserve the Ross procedure for children or very young adults. Even in this situation, it has potential to be a lifetime valve with the ability to grow. This is unique and therefore it is worth the extra surgery required. In addition, even though the pulmonary valve is replaced with a homograft, the use of percutaneous pulmonary valves can deal with any late failures of the homografts.

I think the Ross procedure still has a place in cardiac surgery. There are other options that are available for older patients with less surgery required. However, there is a subset of patients that Dr. Oswalt has mentioned that include children, young adults, and perhaps certain cases of endocarditis.

50 Transcatheter Aortic Valve Replacement
Isaac George, G. Russell Reiss, and Mathew R. Williams

INTRODUCTION

Aortic stenosis (AS) is the most common form of acquired valvular heart disease in Westernized nations and its prevalence increases with age. The natural history of untreated AS portends a grave prognosis with 1- and 5-year survival rates of 60% and 32%, respectively. Currently, the only effective treatment for patients symptomatic from AS is surgical aortic valve replacement ( AVR ). In the ideal candidate, the estimated mortality from surgical AVR performed by a skilled operator should be <3%. Historically, the rate of mortality and postoperative complications for surgical AVR have climbed rapidly after the eighth decade of life and in those with multiple pre-existing conditions and comorbidities, such as depressed left ventricular ( LV ) function, associated coronary artery disease ( CAD ), prior cardiac surgery, renal insufficiency, peripheral vascular disease, and chronic lung disease. Because of this increased perioperative risk in the elderly and often frail patient, as many as 30% of patients diagnosed with critical AS never get referred to a surgeon.

First introduced nearly a decade ago, transcatheter AVR ( TAVR ) has been established as a safe and effective alternative to AVR in patients previously considered “high risk” or inoperable due to prohibitive predicted preoperative mortality. There are currently two transcatheter heart valve ( THV ) replacement devices approved for use in the United States, each using a unique platform for delivery and having individual nuances regarding patient workup, clinical management, and device deployment. The Edwards Lifesciences ( Irvine, CA ) SAPIEN™ THV system ( transfemoral: Retroflex 3 [RF3] and newer generation XT; transapical: Ascendra ) are balloon expandable devices consisting of bovine pericardial valve leaflets attached to stent platforms placed in the subcoronary position. The transfemoral SAPIEN RF3 is currently the only THV that is FDA approved for commercial use in the United States for inoperable patients. In contrast, the Medtronic ( Minneapolis, MN ) CoreValve™ Revalving system is a self-expanding, nitinol cage with porcine leaflets, which seats in the LV outflow tract and spans through the aortic valve to above the coronary ostia. Both THV systems will be discussed in this chapter. In addition, several next generation devices are currently without a surgical option or whose risk of mortality exceeds 15%. Hence, the typical TAVR patient is in the top 10% for operative mortality with a Society of Thoracic Surgery (STS) PROM score typically >10 and having a corresponding Logistic European System for Cardiac Operative Risk Evaluation score (EuroSCORE) of >30. Data from multiple well-designed prospective randomized trials have demonstrated that TAVR, although carrying a higher incidence of stroke, is a viable alternative to surgical AVR in patients with this extreme predicted operative risk. However, due to unproven long-term durability and efficacy, TAVR has not been offered in lower risk patients and further study is needed to determine if TAVR will be appropriate in these populations.

Risk assessment for TAVR is not solely for the purpose of evaluating periprocedural mortality, however. A more important function of risk assessment in this population is to better understand the natural history of patients treated with TAVR. It is well documented that surgical models of risk fail to capture the true risk of patients with severe comorbidity while overestimating risk in elderly patients, and offer little validation in the current TAVR population. Furthermore, models of surgical risk provide no information regarding important clinical variables such as cost-effectiveness, long-term morbidity, and noncardiac mortality, which are all vital in determining which patients should be treated with TAVR. For that reason, risk assessment must take into account both traditional methods of risk scoring, such as the STS and EuroSCORE systems, which
are based on historical data of outcomes from coronary and valvular surgery, as well as newer, nontraditional methods, such as frailty scoring and adjusted incremental risk. A frailty index used at our institution has proven to be invaluable to our assessment and its components are described in Table 50.2. In addition, taking into account factors not integrated in the STS or EuroSCORE, such as pulmonary hypertension, cirrhosis, and dementia, can weigh heavily in final patient selection. In general, any patient with a life expectancy of less than 12 months due to a noncardiac condition or with such severe medical comorbidity (i.e., extreme frailty, moderate-to-severe dementia, etc.) that will prevent meaningful recovery should not be offered TAVR. A comprehensive list of relative exclusion criteria pooled from existing clinical trials is provided in Table 50.3.

Appropriate patient selection and screening is crucial to maximize the chance of procedural success. Once a patient has been deemed a nonoperative or high-risk surgical candidate, the primary determinants of TAVR eligibility initially focus on aortic annulus sizing and anatomy and route of device delivery. Table 50.3 lists the current annulus sizing criteria for patients eligible for both the SAPIEN and Core Valve THV. Patients with extremely small or large annuli (<18 or >25 mm) may face a higher risk of aortic/ventricular rupture or severe paravalvular leak (PVL), respectively, with current devices, and should be avoided for THV use until suitable devices are available. There are a number of anatomic considerations that may also preclude TAVR success: (1) noncalcified valves may not provide adequate annular support for an expanded valve stent and have not been studied, (2) patients with unicuspid or congenital bicuspid aortic valves may not allow proper THV stent expansion, (3) patients with leaflet thrombus or vegetation are not THV candidates, (4) placement of a THV in the presence of low-lying coronary ostia, bulky calcified leaflets, or an effaced sinus of Valsalva may result in coronary obstruction, and careful consideration for coronary vessel access must be made prior to THV deployment, and (5) patients with severe aortic insufficiency should be evaluated with caution. Inadequate characterization of this complex anatomy may lead to serious procedural morbidity; complications have included valve migration and embolization, annulus rupture, aortic dissection, and severe PVL. Many of these complications can be avoided with careful planning.

The delivery of THV may be performed by either a transfemoral or transapical approach. The transfemoral approach consists of retrograde percutaneous delivery through femoral artery access, while a transapical approach requires a mini-left thoracotomy for LV apical exposure, followed by percutaneous antegrade delivery via the LV apex. Advantages to both routes exist but patient considerations usually dictate the approach. In patients with suitable femoral access, a transfemoral approach may be preferable to transapical, as pain and recovery from mechanical ventilation may be reduced. However, in patients with poor vascular access, the transapical approach offers a safe and direct means for device delivery. To date, both access routes have shown equivalent outcomes versus surgical AVR. Vascular size criterion for transfemoral access for both the Edwards SAPIEN and Medtronic CoreValve systems, as well as inclusion/exclusion factors, is described in Table 50.4.

Successful alternative methods of THV delivery have been reported as off-label use and/or outside the United States. These routes, such as direct-aortic (through a hemi-sternotomy or right third intercostal space parasternal exposure), subclavian or axillary artery cutdown, or via abdominal aorta conduit, present separate technical challenges in terms of surgical exposure and device deployment, and should only be performed when necessary and by highly qualified operators. To date, placing a THV into a bioprosthetic valve has been performed worldwide with some success in isolated cases, but full evaluation of these techniques have not been documented and are beyond the scope of this chapter.

ADL, activity of daily living; AVR, aortic valve replacement.

### Table 50.3: Relative Contraindications to Transcatheter Aortic Valve Replacement

- Congenital unicuspid or bicuspid, or noncalcific
- Mixed aortic valve disease
- Hypertrophic cardiomyopathy with or without obstruction
- Ejection fraction <20%
- Severe pulmonary hypertension or severe right ventricular dysfunction
- Echocardiographic evidence of intracardiac mass, thrombus, or vegetation
- Anulus sizing <18 or >29 mm
- Significant aortic disease
- Severe mitral regurgitation
- Life expectancy <12 mo
- Moderate-to-severe dementia
- Extreme frailty
- Futility of medical care due to comorbidities or severity of cardiac disease

**PREOPERATIVE EVALUATION**

Preoperative testing for patients being considered for TAVR is comprehensive, as...
both eligibility for valve placement from an anatomic standpoint must be determined, as well as testing for fitness to tolerate the procedure in this sick cohort of patients.

Evaluation of the aortic valve, aortic root, and peripheral vasculature provides the necessary clinical information to confirm eligibility for TAVR. The echocardiogram is the primary modality to document the severity of AS and size the aortic valve annulus (see Table 50.1 for echocardiographic description of severe AS). Valuable information regarding the calcium severity of the leaflets, valve type (uni-, bi-, or tricuspid), annulus to coronary ostia height, and leaflet length and bulkiness may also be obtained. Note that measurement in the parasternal long axis views and during systole most accurately size the annulus (Figs. 50.4A and B). Preoperative transthoracic echocardiography may be sufficient for most patients, but transesophageal echocardiography (TEE) should be utilized in the event of any discrepancy or concern. Low gradient in the presence of low-ejection fraction is frequently encountered in high-risk and elderly patients; in these cases, dobutamine stress echocardiography is mandatory to evaluate contractile reserve and candidacy for TAVR.

Multidetector computed tomography (MDCT) angiography (CTA) of the chest, abdomen, and pelvis with iliofemoral runoff is performed, detailing the anatomy of the aorta and aortic root, with special attention given to aortic root size, aortic tortuosity and angulation (especially at the arch), calcification, areas of stenosis, and adequacy of peripheral vessels for the transfemoral approach. Iliac angiography or computed tomography (CT) reconstruction of peripheral vessels is mandatory to confirm vessel adequacy for the transfemoral approach (see Table 50.5 for minimum vessel size for TAVR). Aortography may be used selectively as an adjunct to echocardiography and CT scanning. Iliac intravenous ultrasound can be substituted for CTA scan to avoid intravenous dye administration in patients at risk of renal failure.

A standard right and left heart cardiac catheterization should be performed to evaluate the presence of pulmonary hypertension and any concomitant CAD. Depending upon the severity, certain coronary lesions may need to be addressed prior to consideration for TAVR. The use of systemic anticoagulation or platelet inhibitors should not affect TAVR candidacy, although TAVR within 1 month of bare-metal stent placement and within 6 months of drug-eluting stent placement is not recommended. Finally, other comorbidities, such as advanced pulmonary disease, chronic renal insufficiency, and ongoing gastrointestinal disease should be addressed as part of a standard preoperative workup.

**CURRENT TRANSCATHETER HEART VALVE TECHNOLOGY**

**Edwards SAPIEN and SAPIEN XT**

The Edwards SAPIEN THV is a balloon-expandable bioprosthesis that is available in two sizes, 23 and 26 mm (Fig. 50.1A). The valve leaflets are made from bovine pericardium that has been pretreated to

reduce calcification and functional deterioration. The leaflets are suspended on a stainless steel cage, which is 14.3 or 16.1 mm high for the 23 and 26 mm (Fig. 50.1C), respectively. There is a fabric cuff in lieu of a sewing ring residing on the ventricular side that covers approximately one half of the valve. This fabric is designed to limit overexpansion and reduce PVL. The SAPIEN XT is a newer generation THV mounted on a cobalt-chromium alloy cage that allows for a lower profile and smaller device sheath size at the equivalent radial strength (Fig. 50.1B). The effective orifice area of both the SAPIEN and CoreValve valves are larger and provide lower hemodynamic profiles than their corresponding surgical valves.

For the transfemoral approach, SAPIEN and SAPIEN XT THVs are delivered across the aortic valve through the Retroflex 3 Guiding Catheter or Novaflex Delivery System, respectively. For transapical access, the Ascendra I system is the only delivery system available for SAPIEN THV. All SAPIEN THV are designed to seat at the annulus at its lowest level, while the stent frames cross over the coronary ostia at the upper stent segment. Differential radial strength (high at lower inlet portion, low with limit at the middle portion at the level of coronaries, and flared at the upper portion) is designed to reduce the incidence of coronary obstruction; however, a possible downside to this feature is potential difficulty in future coronary interventions. All CoreValve THVs are delivered via transfemoral access at this time.

The CoreValve requires manual loading onto the delivery system by means of a disposable loading apparatus. Given the overall long length of the stent frame, manipulation of the device catheter across an angulated aortic arch may pose technical challenges.

Medtronic CoreValve ReValving System

The Medtronic CoreValve THV is a self-expanding bioprosthetic valve available in three sizes: 26, 29, and 31 mm (Fig. 50.1C). Three porcine pericardial leaflets are attached at the level of smallest diameter on a 53 to 55 mm tall nitinol stent frame. A pericardial skirt at the inflow is aimed at securing the valve and minimizing PVL, similar to the Edwards SAPIEN valve. The valve is seated at the annulus at its lowest level, while the stent frames cross over the coronary ostia at the upper stent segment. Differential radial strength (high at lower inlet portion, low with limit at the middle portion at the level of coronaries, and flared at the upper portion) is designed to reduce the incidence of coronary obstruction; however, a possible downside to this feature is potential difficulty in future coronary interventions. All CoreValve THVs are delivered via transfemoral access at this time.

General Preparation

To reduce infection risk, prophylactic antibiotics are administered similar to any open surgical aortic valve replacement imaging modalities, and the varied skill sets needed at the procedure table, a highly functional heart team is essential for success. This model has been established in all current U.S. TAVR centers, as outlined in the latest ACCF/AATS/SCAI/STS Consensus Document on Transcatheter Aortic Valve Replacement (2012).

A hybrid room with full catheterization, hemodynamic, and cardiopulmonary bypass surgical capabilities has been utilized for TAVR to allow centralization of the team, manage various access routes in the same operating room, and deal with complications rapidly. Nursing, angiography support staff, and surgical staff may require cross-training in other specialties in order to be fully functional in the hybrid room and with all aspects of the procedure.
and should be continued through the perioperative period, usually 24 to 48 hours. Aspirin and clopidogrel are given preprocedure and are continued for at least 6 months. Patients are scrubbed and draped for sternotomy in the event of an emergency. In addition, selection of peripheral cannulas for cardiopulmonary bypass should be made prior to intervention should cardiopulmonary bypass need to be instituted from the groin.

**Transfemoral Approach**

**Vascular Access**

Vascular access for TAVR may be achieved for the transfemoral approach by either a fully percutaneous approach or surgical cutdown. Early THV using a surgical cutdown may be preferred until sufficient experience with the procedure is obtained.

If a percutaneous approach is chosen, meticulous technique for venous and arterial access is paramount, given the large sheath sizes, need for anticoagulation, duration of procedure, and potential for unrecognized retroperitoneal bleeding.
Percutaneous femoral access is first achieved on the contralateral side (side opposite to that intended for THV deployment sheath); a 5F arterial sheath is placed first, accommodating a 5F pigtail catheter, which is inserted into the aortic root. This is followed by a 6F venous sheath in the femoral vein for the passage of a temporary transvenous pacemaker (TVP). Once positioned in the posterior wall of the right ventricle, the TVP is tested for capture with a low diastolic threshold. Prolonged hypotension should be avoided at this point, as AS remains uncorrected at this stage and systemic recovery from profound hypotension may be compromised.

Fig. 50.3. Valve positioning and deployment. (A) Edwards SAPIEN valve positioned across aortic valve—transfemoral. (B) Edwards SAPIEN valve positioned across aortic valve—transapical. (C) Transfemoral Edwards SAPIEN RF3 valve postdeployment.

Shortly after vascular access is obtained, initial aortic angiography via the pigtail catheter is performed confirming the best image projection for deployment. An ideal projection plane is one that lines up all three aortic cusps in a single planar image, while making the valve cusps orthogonal to the image intensifier (Fig. 50.2A). The importance of correctly identifying this image cannot be understated; inaccurate deployment views may lead to severe PVL, coronary obstruction, valve migration, or embolization. Frequent views that we have used include left anterior oblique-caudal, straight anteroposterior, and slight left anterior oblique-cranial, but standardization is impossible due to differing patient anatomy. Third-party imaging software such as angiographic reconstruction programs (DynaCT, Siemens, Germany; Paion, Inc., Rosh Haayin, Israel) may aid in finding this optimal view.

Access on the delivery sheath side (ipsilateral) is accomplished either by surgical cutdown or percutaneous methods, as previously mentioned. If a surgical cutdown is chosen, a 3 cm transverse incision above the inguinal crease is made. Dissection down to the femoral sheath is performed to expose the anterior surface of the common femoral artery and vein, located below the inguinal ligament. Vascular control of the iliac and common femoral artery upon deployment views may lead to severe PVL, coronary obstruction, valve migration, or embolization. Alternatively, a fully percutaneous method of device sheath delivery is now more common than surgical exposure. In experienced hands and with smaller delivery sheaths, a percutaneous success rate >95% can be achieved. In this approach, the 10F Prostar (Abbott Vascular, IL) two-suture percutaneous closure can be used to “pre-close” the THV access artery. To begin, ipsilateral arterial access is carefully gained with a 5F sheath, and proper location is confirmed angiographically. Entry should be located between the inferior epigastric artery and the femoral bifurcation over the femoral head. Prostar stitches are delivered through the arterial wall over a standard 0.035 J-wire, and untied stitches are secured for tying postprocedure. Concurrently, intravenous heparin is administered to maintain an ACT >200 throughout the case.

The ipsilateral access side is serially dilated with increasingly larger French shears over a extra stiff wire, typically beginning with 12F to 16F and ending with a dilator 1F to 2F smaller than the device sheath size. Continuous fluoroscopy during advancement of dilators is necessary, and issues of tortuosity, calcification, or wire kinking may need to be addressed at this time. After final dilatation, the large device sheath is carefully advanced and positioned in the descending thoracic aorta.

Balloon Aortic Valvuloplasty

Attention is turned to preparation for crossing the stenotic aortic valve. In the deployment view, the aortic valve is crossed using a straight stiff glide wire through a Amplatz left 1 or 2 catheter (Cook, Bloomington, IL) positioned in the aortic root. Once across the aortic valve, the catheter is advanced into the left ventricular outflow tract and the glide wire is exchanged for a 0.035 Amplatz extra stiff guidewire with a large preshaped loop to allow seating in the LV and minimize ventricular ectopy. Careful control of the wire in the ventricle must be maintained at all times throughout deployment, as aggressive manipulation can easily result in ventricular perforation. A baseline gradient should be measured just prior to this wire exchange to confirm the severity of AS and allow for hemodynamic comparison post-THV deployment. Next, a BAV is chosen based on annulus size (2 to 4 mm less than annulus size). At this point, prior to BAV, the THV should be crimped and ready on the back table in the event of severe aortic regurgitation (AR) or hemodynamic instability. The BAV is performed expeditiously under temporary rapid ventricular pacing when the mean blood pressure is <40 mmHg (Figs. 50.2B and C). There should be minimal distraction in the room at this time, and clear and deliberate commands to the person operating the TVP must be given. Rapid pacing is continued
until full inflation. The balloon is then rapidly deflated, the pacer is turned off, and the balloon is removed. Improved excursion of the valve leaflets with increased regurgitation should be apparent by TEE with a suitable BAV (Fig. 50.4B).

Valve Deployment

Next, the valve itself is checked for orientation on the valve delivery system prior to insertion into the sheath. The combination THV delivery system is inserted through the large sheath and slowly advanced retrograde through the aorta. At the level of the aortic notch, the delivery system is carefully guided across the aortic arch (the retroflex steering system is activated if an Edwards SAPIEN THV is used, creating a curved angle in the catheter). At the level of the stenotic aortic valve, slight backward tension is placed on the wire while advancing the valve across the aortic valve. Once across the aortic valve, the flexible portion of the delivery catheter is moved back on the wire away from the valve.

The position of the valve is checked both by TEE as well as fluoroscopy. For the Edwards SAPIEN valve, an ideal position seats the mid-portion of the stent directly across the presumed aortic annulus in approximately 50% aortic, 50% ventricular proportions (Figs. 50.3A, B and 50.4C). Once position is confirmed, rapid pacing is again instituted; the position is confirmed by TEE while pacing, capture is confirmed by visual and hemodynamic standstill, and the valve balloon is smoothly inflated, deploying the valve. The pacer is then turned off, and the rhythm and blood pressure are allowed to stabilize. For the Medtronic CoreValve, the valve is seated at the annulus and extends into the ascending aorta. Deployment occurs without ventricular pacing or balloon expansion, and some tolerance for repositioning of the valve exists, unlike the SAPIEN valve.

The device balloon is then rapidly deflated (Edwards valves only), and the balloon is drawn back into the ascending aorta. The stiff wire is left in place while immediate assessment of valve integrity and function is confirmed by TEE (Fig. 50.4D); immediate complications such as annular disruption, ventricular perforation, and valve migration may be readily apparent if present. At this point, hypotension is often present but tends to be transient with proper valve deployment. Communication with anesthesia should be continuous here as to not overcompensate with medication, as severe hypertension has been associated with stroke, periaortic hematomas, and root rupture. The TEE is the most useful tool for immediate assessment of valve function and the presence of AR and PVL. In the presence of greater than mild PVL, we frequently add an additional 0.5 to 1.0 cm$^3$ of saline to the deployment balloon and a repeat inflation is performed under rapid pacing. This can generally improve the PVL by one grade, although the long-term effect on valve durability has yet to be determined.

Vascular Access Site Closure

Once the valve position and function are confirmed to be satisfactory, the THV delivery system can be removed with deactivation of the retroflex function upon exiting the aortic arch to straighten the catheter and removed from the device sheath (Fig. 50.3C). If a surgical cutdown was performed for access, surgical closure is performed following device sheath removal under direct vision.

For fully percutaneous access, we routinely perform a cross-over balloon technique that utilizes a contralateral balloon for the control of the iliac. In brief, an Omni catheter (Angiodynamics,
Latham, NY) over an angled glide wire is placed in the contralateral side and maneuvered into the device sheath distally until at the ipsilateral access site. The Omni catheter is replaced with a 7F Ansel catheter (Cook Medical, IN) over a stiff wire. A peripheral occlusion balloon (usually an 8 or 10 mm) is placed in the ipsilateral common iliac through the Ansel catheter, and the Prostar sutures are prepared. The device sheath is then moved back to just above the ipsilateral access site, the peripheral balloon is inflated to fully occlude flow distally in the ipsilateral iliac, and the Prostar sutures are tied as the device sheath is removed. Once the sutures are secure, the iliac balloon is deflated and a femoral angiogram is performed. Most post-THV extravasations less than severe can be adequately controlled with redeploying the occlusive balloon at the site of the arteriotomy, reversing the heparin, and applying manual pressure. In the event of a percutaneous closure failure, the presence of percutaneous balloon control of the proximal iliac allows for controlled open vascular repair with a minimal incision or peripheral covered stenting from the contralateral access.

If no significant changes in heart rhythm are encountered, the TVP may be safely removed at the conclusion of the case, and manual pressure applied to the venous catheter site.

**Transapical Approach**

The transapical approach mirrors the transfemoral approach conceptually: transapical access, device sheath placement, crossing the valve, BAV, and then valve deployment. Hemodynamic changes and AR after BAV are tolerated less with a large device sheath impeding flow in the ventricle; therefore, operators must move quickly between steps should hemodynamic compromise occur. Anesthetic and team considerations all apply to the transapical approach, and the hybrid room may need to be modified to accommodate the image intensifier, operators, and echocardiogram machine all near the head of the bed. Note that at this time, the transapical route of delivery is approved only for the Edwards SAPIEN THV, using the Ascendra delivery system.

**Transapical and Vascular Access**

The patient is positioned on the table with special attention given to the left chest area where a mini-anteralateral thoracotomy incision will be made. In women with large breasts, a plastic surgical drape may be used to pull the breast toward the head and away from the breast crease. Arterial (5F) and venous (6F) access in the femoral vessels is gained on side best suited for cardiopulmonary bypass in an emergency, and a TVP is positioned as described previously. A clamp placed on the left chest is then imaged to identify the LV apex and proper rib space in which to enter—this location is used to make a 4 cm incision, usually in the fourth or fifth intercostal space. Dissection is carried down to the intercostal fascia. The pleura is carefully entered after ventilation is temporarily held, and LV apex location is palpated. If the apex is not accessible from the current incision, entry one rib space above or below is still an option. An area just superior to the apex is usually most suitable for entry, and this spot is verified by manually identifying the ventricular wall with a finger while observing the location on TEE. The true apex is avoided as the entry site, due to thinning of the apical wall and frequent scarring after myocardial infarction. Adhesions and pericardial fat surrounding the LV apex...
are cleared. A longitudinal pericardiotomy is made large enough to expose an area for apical sutures; stay sutures are placed if the patient has not had prior cardiac surgery. If the patient has had prior cardiac surgery, we make a small pericardiotomy just large enough to accommodate the device sheath, but place our apical sutures directly through the pericardium—the adhesed pericardium acts to buttress the ventricular tissue when tying sutures. Apical sutures with soft felt pledgets are placed in a 3 × 3 cm area centered on the previously identified entry site. We typically place two U-shape stitches with felt pledgets using a 2-0 polypropylene suture on a large needle, although others have used a purse-string with success. Given the fragility of elderly ventricular tissue and labile blood pressure after valve deployment, all stitches must be precise, exact, and with perfect technique to prevent tearing of the ventricular tissue. Stitches placed too shallow may not hold, and apical site bleeding can quickly become fatal. Once the apical stitches are placed, the patient is heparinized for an ACT >230.

The optimal deployment view is determined at this stage. The deployment view may vary greatly in the transapical approach, and the positioning of the operators near the left head-side of the table often limits the full range of the C-arm. We find a slight left anterior oblique with slight caudal views allows good visualization of the surgical field as well as a reasonable deployment view.

Access to the apex is achieved by placing an introducer needle directly into the center of the sutures. Extreme care must be made to ensure that this needle stick is centered within the sutures—if outside, the sutures will tighten the tissue but will not close the bleeding apical entry site. A J-wire is passed retrograde across the aortic valve through the access needle, and positioned in the descending aorta. A Judkins right catheter is placed in the descending aorta over the J-wire. An Amplatz stiff wire is passed through the Judkins catheter into the descending aorta, and the catheter is removed. Minimal bleeding from the access site is seen at this point. The stiff wire is held perpendicular to the access site, as angulation of the exposed wire may saw into the fragile ventricular tissue and cause more bleeding.

The 26F Ascendra I device sheath is now advanced into the ventricle to the 4 cm mark under fluoroscopy over the stiff wire. Significant bleeding around the sheath occasionally occurs, and gentle tightening of the sutures may lessen bleeding. Note that this maneuver can also result in unwanted tearing of ventricular tissue leading to life-threatening disruption of the LV free wall. Hence, aggressive cinching of apical sutures should be avoided, with expeditious THV deployment followed by quick removal of the sheath being favored whenever perisheath bleeding is encountered. Control of the device sheath must be maintained at all times by an operator—motion of the device sheath may severely impact BAV, valve deployment, and bleeding.

### Balloon Aortic Valvuloplasty

A BAV balloon is next brought across the aortic valve, and a BAV is performed under rapid pacing, as previously described for the transfemoral approach. Sizing for the BAV balloon follows the same guidelines as the transfemoral approach. The balloon is rapidly removed after deflation.

### Valve Deployment

The THV delivery system is now loaded into the device sheath, and the valve is advanced to the end of the device sheath (still inside the ventricle). An important detail for every case is to check the orientation of the valve—for the transapical retrograde approach, the THV is loaded in opposite manner from the transfemoral approach. Once well beyond the device sheath yet still in the ventricle, the delivery sheath is pulled back from the THV. Preparation for deployment is made by all members of the team: operators, anesthesia, and ancillary staff. Tension is held on the stiff wire, while the THV crosses the native stenotic aortic valve. Positioning is confirmed by TEE as well as pacing aortogram if necessary; subtle movements of the valve can be controlled by moving the entire device sheath rather than the THV, to avoid stored tension in the wire. Slack on the stiff wire can also alter the position of the valve—removing the slack with tension will move the valve closer to the left coronary cusp. The valve is positioned 50% ventricular and 50% aortic based on patient anatomy.

Deployment occurs under rapid pacing with balloon inflation after position confirmation by TEE and fluoroscopy. After deployment, the balloon is quickly moved back into the device sheath, and PVL is evaluated by echocardiography. If no significant PVL is identified, the wire and balloon are removed from the device sheath. Ventricular apical sutures are prepared for tying, while ventricular pacing is used to reduce the systemic blood pressure below 100 mmHg. Once a target blood pressure is reached, the sheath is removed and the two sets of sutures are tied down. Rarely, central leaking from the suture line is seen and is easily controlled with a single suture through the pledgets. Bleeding with systole from outside the pledged suture area not only may be benign and resolve with pressure or hemostatic agents but may also signal a more serious ventricular tear beneath the visible sutures. Additional sutures may help, but significant bleeding from the apex should be addressed by instituting cardiopulmonary bypass peripherally, followed by appropriate repair of the apex with a decompressed ventricle.

### Closure

Reversal of heparin with protamine is performed if any concern for bleeding exists. The femoral access site is closed with a Perclose device, while the TVP is removed and pressure applied to the venous access site. In patients with no prior cardiac surgery, one 3-0 absorbable suture stitch is placed to reapproximate the pericardium. The thoracotomy is closed in layers with absorbable suture; sutures to close the rib space are unnecessary. A generous intercostal nerve block with topical anesthesia is given and appears to have a noticeable reduction of postoperative pain. A 9F Blake drain is placed in the pleural space.

### Clinical Outcomes

The Edwards SAPIEN RF3 THV valve and delivery system were approved for use in symptomatic severe AS in inoperable patients based on data from the PARTNER trial, a prospective, randomized controlled trial conducted in the United States. Each potential patient was screened jointly by investigators and enrolled into cohort A, high-risk surgical candidates, or cohort B, inoperable patients, and met criteria for severe AS.

Patients in cohort A were randomized to either surgical AVR or TAVR (transfemoral or transapical based on vascular access), while patients in cohort B were strictly randomized to medical treatment versus TAVR by transfemoral access; transapical delivery was not an option in cohort B patients with inadequate vascular access. Patients were otherwise defined as inoperable if the risk of mortality or serious morbidity exceeded 50%, roughly corresponding to a logistic STS score >15. The primary endpoint in cohort A was freedom from all-cause death at 1 year, with secondary endpoints of rate of death from cardiovascular causes, NYHA functional class, the rate of repeat hospitalization due to valve-related or procedural
clinical deterioration, the distance covered in a 6-minute walk test, valve performance, and the rates of myocardial infarction, stroke, acute kidney injury (AKI), vascular complications, and bleeding. For cohort B, the primary endpoint was freedom from death over the trial period (1 year), and a composite endpoint of death and recurrent hospital readmission.

TAVR met criterion for noninferiority when compared with surgical AVR in cohort A patients at 1 year (overall mortality: 24.2% vs. 26.8%; hazard ratio: 0.93; 95% confidence interval: 0.71 to 1.22; P = 0.001 for noninferiority; see Table 50.6). The study was not powered to compare transfemoral versus transapical outcomes, but it is notable that the outstanding surgical outcomes at 30 days (mortality 6.5%) were far lower than expected by risk calculations (STS score: 11.8%). Each treatment arm experienced adverse events at 1 year: in TAVR patients, a higher rate of major stroke (5.1% vs. 2.4%) and vascular complication (18.0% vs. 4.8%) was seen, while major bleeding (25.7% vs. 14.7%) was more common after surgical AVR.

TAVR demonstrated a dramatic survival benefit for patients in cohort B: all-cause mortality was decreased from 49.7% in medically treated patients to 30.7% in patients undergoing TAVR at 1 year (P < 0.001; see Table 50.7). Event-free major

AVG, aortic valve gradient; EOA, effective orifice area; MACCE, major adverse cardiac and cerebrovascular events; TAVR, transcatheter aortic valve replacement.
adverse cardiac and cerebrovascular events and almost all functional endpoints were significantly improved after TAVR. Yet, concern has been raised over the higher rate of stroke experienced in the TAVR arm (11.2% vs. 4.5%; \( P = 0.03 \)) and vascular complications (17.3% vs. 2.2%; \( P < 0.0001 \)), although it is expected that vascular complications will lessen with smaller delivery systems.

**POSTOPERATIVE CONSIDERATIONS**

**Complications**

TAVR is associated with a steep learning curve during which time the operative team will face numerous unforeseen challenges. Expert opinion indicates an experience between 30 and 100 cases being needed before a competency plateau is reached where an individual heart team can reliably manage the majority of complications faced during a TAVR procedure. As such, most periprocedural complications are related to lack of operator experience, interpreting complex three-dimensional anatomy through two-dimensional imaging, and understanding the nuances of clinical management unique to the fragile TAVR patient. Rarely, a particular THV prosthesis may malfunction; however, this has become increasingly less common, particularly with later generation THVs. Although not strictly considered a complication, many heart teams find themselves managing numerous complications in their early experience secondary to poor patient screening and selection.

**Strokes and Transient Ischemic Attacks**

The incidence of clinically significant “major” stroke, defined as a modified Rankin score >2, after TAVR has been reported between 2.9% and 8.4% at 30 days and 1 year, respectively, depending upon the access approach and device deployed. This incidence is significantly higher than the 2.1% and 2.4% rates for surgical AVR reported in the literature for similar matched cohorts. The etiology of most cerebral vascular events in the TAVR patient is related to embolization of atherothrombotic material during device delivery and deployment. The source of embolic material is thought to be from the aortic arch and heavily calcified valve leaflets. In addition, periprocedural hypotension and hemodynamic instability, in conjunction with pre-existing patient comorbidities such as advanced age, hypertension, atrial fibrillation, peripheral vascular disease, and diabetes all contribute to the overall stroke risk. Recent magnetic resonance imaging-diffusion weighted imaging (MRI-DWI) microembolism studies have reported the incidence of cerebral ischemic lesions post-TAVR to be as high as 68% to 84%. However, the clinical significance of these data is not apparent. Currently, novel cerebral protection devices are under development, as stroke risk will need significant mitigation prior to TAVR becoming an acceptable option in younger or lower risk candidates. The incidence of stroke may also lessen as patient selection becomes more refined, delivery systems improve in their profile, and protocol-driven antithrombotic regimens are routinely used during TAVR.

**Conduction System Disturbances**

Conduction abnormalities are frequently seen in patients undergoing TAVR with an incidence higher than that historically seen in surgical AVR. Pre-existing conduction defects, extent of aortic leaflet and annular calcification, interventricular septal thickness and final prosthesis position, which can cause mechanical impingement of the conduction system, are all associated factors. The incidence of complete heart block after TAVR ranges from 19% to 22% with pre-existing right bundle-branch block being a risk factor contributing to its development and the need for subsequent pacing. The incidence of complete heart block requiring permanent pacemaker implantation has been higher with the Core Valve than with the SAPIEN valve potentially due to its larger profile and lower extension into the LV outflow tract. The incidence of new left bundle-branch block varies widely ranging from 14% to 83%. The majority of conduction abnormalities occur in TAVR prior to THV deployment, with nearly 70% attributable to wire-crossing of the aortic valve, BAV, and prosthesis positioning. The remaining events likely occur during THV expansion. Although permanent pacemaker implantation has not been shown to negatively effect survival, continuous perioperative telemetry should be routine in all patients undergoing TAVR, with longer monitoring required for those patients with known conduction abnormalities or those receiving a Core Valve device.

**Vascular Complications**

Pre-existing vascular disease ubiquitous to the TAVR population combined with large caliber sheaths necessary for THV delivery makes vascular complications the most frequent adverse outcome associated with TAVR. The incidence of major vascular complication for transfemoral access ranges from 2% to 26% and it has reported to be between 5% and 7% for transapical TAVR. Although of lower incidence, transapical complications, when they arise, are more likely to be fatal. Vessel size, tortuosity, degree of aortoiliac occlusive disease, calcium burden, and sheath-to-artery ratio along with operator experience are all predictors of major vascular complications. As operator experience increases, vascular complications become easier to anticipate and mortality decreases. Aortic occlusive balloons and cross-over catheters should be accessible to minimize bleeding and stabilize the patient in the event of a major vascular complication. The Valve Academic Research Consortium (VARC) has classified the major vascular complications associated with TAVR to include aortic dissection, perforation, rupture, bleeding requiring significant blood transfusions, or additional percutaneous or surgical intervention. In an attempt to limit vascular complications, a growing experience with alternative approaches including transaortic and subclavian access is underway in several centers.

**Aortic Regurgitation and Paravalvular Leak**

AR is commonly noted immediately post-TAVR, occurring at an incidence of 85% with up to 75% of patients still experiencing mild or more AR at 1 year, and one-third having more than mild. AR post-TAVR can be categorized according to etiology, as either valvular or paravalvular. In addition, it should be further characterized as to its location, severity, and cause with an estimate of overall volumetric impact calculated at time of recognition. Most valvular AR is central and attributable to the guide wire remaining across the prosthesis after deployment and immediately resolves upon withdrawal of the wire. Residual central AR, however, results from improper sizing or deployment. Diligent pre-procedural planning utilizing both echocardiography and MDCT for annular analysis is important in order to appropriately size the valve compared with the annulus. Rarely is AR caused by THV malfunction but when this scenario occurs it may be related to prosthesis damage imparted during the crimping process. In the setting of Core Valve, low positioning of the frame can result in significant AR and can be resolved by snaring the frame loops and correctly repositioning.
Improper THV positioning can lead to forward aortic blood flow. Subsequent outcomes. At this time, hemolysis is not a failure. Ventricular embolization requires efforts should be made to maintain orientation such as to allow persistent blood flow. In patients with prior CABG, the left main coronary artery may be protected by patient bypass grafts in which case occlusion of the coronary ostia is of less consequence; however, preparedness for rapid PCI or surgical revascularization is paramount should acute ostial occlusion with associated hemodynamic instability arise.

Valve Malposition and Embolization

Improper THV positioning can lead to instability, migration, and embolization. If recognized in a timely manner, an unstable prosthesis can be remedied by rapid placement of a second overlapping valve-in-valve. If embolization into the ascending aorta occurs, immediate efforts should be made to maintain wire access through the THV keeping its orientation such as to allow persistent forward aortic blood flow. Subsequent maneuvers are then aimed at delivering the valve into the descending aorta to a final resting location where it can be permanently fixed by balloon re-expansion in the appropriate orientation. Once the original valve is stabilized, a second valve deployment can be attempted depending on the reason for the initial deployment failure. Ventricular embolization requires urgent surgery; however, this complication is near uniformly fatal.

Coronary Obstruction

Coronary obstruction post-TAVR is a rare concern occurring with an incidence of <1.0%. It occurs less frequently with the SAPIEN THV than with the CoreValve system and can usually be avoided with careful MDCT imaging and thorough pre-procedural aortic root analysis. Longitudinal remodeling, degenerative changes associated with AS, and sinotubular junction effacement can all result in a shortened distance between the coronary ostia and the aortic annulus. These factors combined with heavy leaflet and annular calcium burden predispose a patient to coronary obstruction. Acute occlusion can be recognized by characteristic regional hypokinesis, best appreciated from the transgastric view of the TEE and by evaluating flow in the coronary arteries themselves. In patients with prior CABG, the left main coronary artery may be protected by patient bypass grafts in which case occlusion of the coronary ostia is of less consequence; however, preparedness for rapid PCI or surgical revascularization is paramount should acute ostial occlusion with associated hemodynamic instability arise.

Acute Kidney Injury

AKI after TAVR occurs in up to one-third of patients and results in renal replacement therapy in up to 2%. As with surgical AVR, AKI portends a much higher mortality than those without injury (25% vs. 8%). In comparison to the surgical AVR, TAVR still carries an overall lower incidence of AKI and would appear to be one of its advantages over the conventional approach. Contrast load, pre-existing renal insufficiency, hypertension, transapical approach, and blood transfusion have all been implicated as risk factors for post-TAVR renal failure. In terms of procedural optimization against AKI, recommendations pertain to limiting contrast volume, avoiding intra-procedural extremes of blood pressure, and meticulous vascular access and management. Efforts to avoid other complications that contribute directly to AKI are the mainstay of prevention, with supportive care and optimization of fluid status being the only treatment once AKI occurs.

Next Generation Technologies

One of the immediate needs in the current valve technology is availability of smaller delivery sheath sizes and less traumatic deployment systems. In addition, a broader range of valve sizes is in demand, especially as patient population eligible for TAVR expands. A number of companies have valves in various stages of production and testing, each with slightly different design features: Direct Flow (Lake Forest, CA), Direct Flow (Lake Forest, CA), AortTx (Redwood City, CA), Jena Valve (Munchen, Germany), PercValve (San Antonio, TX), EndoTech SPA (Como, Italy), Ventor Embracer (Medtronic),
Syntesis (Switzerland). It remains to be seen which valves will actually progress to clinical practice.

**Route of Access**
